Permafrost is any subsurface earth material that remains below 0 °C for at least two consecutive years, including the intervening summer. Currently, permafrost covers approximately 25% of the Northern Hemisphere land surface and approximately 25% of the Antarctic continent. Permafrost may also be found as “subsea permafrost” on the seafloor bottom, particularly on the northern continental shelves of North America and Eurasia. In regions where average annual surface air temperatures are 0 °C or less, permafrost develops and thickens because ground freezing penetrates more deeply than summer thawing can reverse. Thus, each year will bring about deeper and deeper frozen ground until the geothermal regime deep within the Earth counteracts this downward freezing process.

Ultimately, equilibrium will be established, therefore providing a stable permafrost depth. Heat conduction through rock and soil can be extremely slow, and depending on the magnitude of a potential surface temperature change, it may take thousands of years before a new thermal equilibrium is established.

Permafrost can be partitioned by areal extent and is typically defined as consisting of continuous (90–100%), discontinuous (50–90%), sporadic (10–50%), or isolated patches (0–10%) (Figure 1). The thickness of permafrost can be quite variable and generally varies between 100 and 800 m (meters) in continuous permafrost, 25 and 100 m in discontinuous permafrost, and 10 and 50 m in sporadic permafrost, yet there is always a seasonally thawed “active layer” at the surface that can vary from centimeters to meters in thickness (Figure 2). The active layer provides an extremely important stratum for activities related to regional geomorphology, vegetation, microbes, soil moisture, and soil carbon stocks. Permafrost soils can be quite complex and may vary tremendously through a vertical column. For instance, arctic soils typically contain organic material at the surface (with compositions ranging from mosses to humus) overlaying mineral soils. Moisture may not necessarily be present in permafrost layers below the active layer: “Dry” permafrost, for example, contains no liquid or solid water. In most cases, however, ice is present (sometimes even in large concentrations as ice wedges) and is a very important factor in the mechanics of permafrost.

Recent Permafrost Degradation

Near-surface permafrost is expected to exhibit significant degradation over the coming century due to current and future climate warming, although this process may somewhat lag behind trends in warming surface air temperatures. Warming air temperatures lead to permafrost thaw and degradation, which can include thickening of the active layer, talik formation, thermokarst development, expansion or creation of thaw lakes, lateral permafrost thawing, and a northward migration of the southern permafrost boundary. These changes can have significant impacts on hydrology, ecosystems, and biogeochemical cycling. Permafrost

warming and degradation may in turn be accelerated by positive feedbacks to include carbon release from freshly thawed soils, projected expansion of shrub cover, and wildfire occurrence.

Three types of permafrost degradation may occur as a result of climate warming: (1) overall permafrost thaw, (2) deepening active layers, and (3) thermokarst processes. Overall or “wholesale” permafrost thaw and thermal degradation result in widespread reductions in permafrost extent, allowing for a connection between deep groundwaters and surface water pathways. As opposed to active-layer and thermokarst processes, time lags involved with wholesale permafrost thaw can be significantly longer, where temperature changes at the ground surface may take from a few years to millennia to reach the bottom of the permafrost layers. Not only can permafrost warm and degrade from the surface as well as from the bottom, but permafrost may also degrade internally if it contains unfrozen water, as seen in some areas of Alaska. Although direct measurements of long-term permafrost dynamics are relatively rare and no real widespread pan-arctic wholesale permafrost thaw has been observed, some studies have in fact shown some substantial local and regional permafrost degradation through field observations. Active-layer thaw depths are also highly responsive to warming air temperatures and can be important indicators of permafrost stability. Deepening active layers may increase the interaction between surface waters and soils within the newly thawed portions of the active layer as well as liberate soluble biogeochemical constituents previously sequestered within the near-surface permafrost. Last, it is also important to address thermokarst processes in the context of permafrost degradation, which is the surface thawing of ice-rich ground and subsequent thaw slumping. Thermokarst is associated with warming air temperatures in discontinuous and sporadic zones of permafrost extent, but it can also occur in regions of continuous permafrost and is not always tied directly to wholesale permafrost degradation.

Impacts of Permafrost Degradation

One of the most important changes to the arctic system caused by ongoing and future warming

Figure 1 Distribution of continuous, discontinuous, sporadic, and isolated permafrost in the Northern Hemisphere

will be the shift from a surface water-dominated system to a groundwater-dominated system. As permafrost degrades and previously frozen soils thaw, significant changes to the flow paths of waters will occur, resulting in profound consequences for hydrology, greenhouse gas emissions,

and biogeochemical cycling. These consequences will be highly complex and will undoubtedly exhibit the spatial and temporal variability associated with current permafrost conditions, sensitivity to thawing, and environmental characteristics of the land surface (e.g., land cover, soil type, and

Figure 2 An example of permafrost distribution in cross section

Source: Pidwirny, M. (2006). Periglacial processes and landforms. *Fundamentals of physical geography* (2nd ed.). Retrieved February 19, 2009, from www.physicalgeography.net/fundamentals/10ag.html. Reprinted with permission.

topography). Some of the most significant impacts of permafrost degradation include those related to (a) terrain stability, (b) greenhouse gas emissions, (c) physical hydrology, and (d) stream and river biogeochemistry.

Extensive thawing of permafrost will have important implications for the stability of the terrain and cause massive surface deformation as ice-rich soil melts. Thermokarst topography is associated with an increase in the depth of the active layer and melting of ice within the ground. This melting leads to settlement and subsidence of the ground in irregular hummocks and depressions containing standing water. This ground subsidence can have massive impacts on human infrastructure such as roads and buildings. Other surface features created by permafrost thawing include retrogressive thaw slumping, active-layer detachment, creep, and enhanced coastal erosion.

Permafrost degradation may also have important implications for greenhouse gas emissions, including both carbon dioxide and methane. The current presence of permafrost in high-latitude regions inhibits percolation of surface water and allows the water table to be sustained close to the

soil surface, thereby maintaining saturated soils or open water surfaces across much of the landscape. These resulting anaerobic wetland regions can be significant sources of methane to the atmosphere. However, permafrost degradation and the subsequent draining of these surface waters exposes carbon-rich soils to aerobic decomposition, which may reduce methane emissions but significantly increase carbon dioxide emissions to the atmosphere. Furthermore, permafrost degradation and thermokarst processes beneath lakes have also been shown to be globally significant sources of methane to the atmosphere. Thawed lake sediments actively produce and emit methane and cause bubbling (or “ebullition”) of methane from lake bottoms and through lake waters to the atmosphere. This resulting methane ebullition is a large and increasing source of atmospheric methane as thermokarst lakes continue to expand with permafrost degradation.

The physical hydrology of systems may also be affected by climate warming and subsequent permafrost degradation. Arctic streams and rivers have experienced observable increases in discharge over the past several decades, with the

thawing of permafrost considered one of many possibilities contributing to this increase. Lakes have also experienced dramatic changes due to permafrost degradation. For instance, in areas of continuous permafrost, lake areas have been shown to grow as thermokarst processes force an increase in lake basin areas. However, in discontinuous permafrost areas, permafrost is sparse enough so that a breach of permafrost layers and sudden connection of lake surface waters with groundwater pathways can cause lakes to disappear entirely. This catastrophic drainage and disappearance of lakes can have many cascading implications that include impacts on the land-atmosphere exchange of carbon, water, and energy but they also may have severe impacts for migrating waterfowl that rely on these wetland and lake-rich areas as breeding grounds.

Permafrost currently underlies significant portions of the six largest Arctic watersheds (Ob', Yenisey, Lena, Kolyma, Mackenzie, and Yukon rivers) in addition to many other smaller streams and rivers entering the Arctic Ocean. As such, profound impacts will occur here with permafrost degradation, including biogeochemical cycling within these watersheds and the resulting delivery of organic matter, inorganic nutrients, and major ions to the Arctic Ocean. One of the most profound consequences of permafrost thaw projected for the future is that the arctic terrestrial freshwater system is likely to experience a transition from a surface water-dominated system to a groundwater-dominated system. Most studies observe or predict an increase in major ion, phosphate, and silica export with this shift toward greater groundwater contributions. However, there are conflicting accounts of whether the delivery of inorganic nitrogen and organic matter will increase or decrease with warming and permafrost thaw. It is clear that over the next century there will be important shifts in the river transport of organic matter, inorganic nutrients, and major ions, which may in turn have critical implications for primary production and carbon cycling on arctic shelves and in the Arctic Ocean basin interior.

PESTICIDES

Pesticides are chemical compounds that kill unwanted organisms, typically insects, fungi, plants, and other pests that harm humans or organisms valued by humans, such as crops and domesticated animals. Pesticides are agrochemicals, a category that includes synthetic fertilizers, which are derived from petroleum and other fossil fuels. Pesticide classification systems include those arranged by the target organisms (insecticide, fungicide, herbicide, acaricides, rodenticide, etc.), by chemical origin ("inorganic" pesticides are derived from basic chemical elements such as copper, "organic" or "synthetic" pesticides from fossil fuels, and "biological" pesticide from organisms), by chemical class (organochlorines, organophosphates, etc.), and by their effects on nontarget organisms.

Farmers producing horticultural crops began widely using inorganic pesticides for pest management in the late 1800s, while synthetic pesticides were widely adopted in many agricultural systems, especially in industrialized agriculture, starting in the 1940s. Today, more than 600 different pesticide active ingredients exist, although

national regulations on these chemicals vary substantially.

Rachel Carson's 1962 famous book *Silent Spring* helped popularize an ecological consciousness through an understanding of the environmental and health effects of chlorinated hydrocarbon pesticides, such as DDT, and the acute toxicity of organophosphate pesticides. The book also inspired the modern environmental movement and the creation of the U.S. Environmental Protection Agency in 1970. Concerns over pesticides and other environmental impacts of agriculture remain an important impetus for promoting organic agriculture. Pesticides are unique in that they are biologically active agents intended to cause harm that are released intentionally into the environment, and as such, their effects are considered externalities of agro-food systems.

Numerous disciplines and fields have become involved in research related to pesticides. Epidemiological and toxicological work has shown pesticides to harm many organisms, including humans. Some pesticides cause acute poisoning, often with long-term effects, while others are carcinogens. Impairment and disruption of the endocrine, immune, and neurological systems has been shown among lab animals at doses near levels currently found in groundwater. Neurological impairment has been demonstrated among pesticide applicators and children in intensive production areas.

Two bodies of geographical work contribute to pesticide research: environmental justice and political ecology. Environmental justice has revealed the unequal distribution of risks and harms in catastrophes such as the Bhopal disaster in 1984 in India; that agribusiness interests strongly shape pesticide regulation, including risk analysis and assessment; and that farm workers as a marginalized population have had less power to influence pesticide regulation except when organized, as the United Farm Workers in California in the 1960s and 1970s. Political ecological approaches to pesticide use involve putting land users' decision making in a broader political economic context by emphasizing agricultural development policies, agrochemical marketing, and regulations, in addition to paying attention to smaller-scale variations such as farmer experiences, land ownership, agroecology, and management and geographical

strategies. Similarly, scholars researching lawn pesticide use in First World contexts have taken a political-ecological approach to show how the chemical industry's need to increase sales shapes land user decision making by promoting a monocultural lawn aesthetic.

PEST MANAGEMENT

The term *pest management* was coined by Australian entomologists in the mid 1960s to denote the active management of pests to human levels of tolerance. Pest management operates at scales

from the individual farm to the national environment but has come to define explicit decision-making frameworks applied to prevent, reduce, or remove the impact of pests on production systems, human health, and the environment. Pest management therefore implies a coordinated management strategy with systematized decision making, in contrast to *pest control*, which refers to the set of actions applied to combat pests in the field. The historical and geographical variation in pest management concerns and regimes, the institutional and legislative frameworks for pest management, and the controversy surrounding pest management techniques are reviewed in this entry.

Pest management emerged historically as industrialization and the mechanization of agriculture prompted a shift from uncoordinated private efforts to control pests, to private firms offering pest control services, to the emergence of public authority oversight. The variation in those species considered pests in different times and places suggests that while a pest can be defined as any organism detrimental to human interests, the production of a pest is the outcome of specific processes. These range from urban health concerns over the plague, rabies, and murine typhus, to mice destroying rice harvests, to badgers spreading bovine tuberculosis on farms, to pigeons as a public nuisance in Trafalgar Square. The history of pest management also demonstrates a broadening of concern from agriculture and public health in metropolitan areas, to environmental impacts of pests such as biodiversity loss. It is perhaps the act of protecting a particular space or desirable entity (such as a residential area, a monoculture crop, or a native ecosystem) that “creates” new pests, through competition for food and habitat between humans and other animals. Research on human-animal conflicts suggests that these are spatial conflicts and challenges to our spatial categorization processes. The classification of a species as a pest is also related to a perceived excess of population numbers (too many wolves and the animal is viewed as a virulent pest, too few and it is a highly valued endangered species). But just as such species are categorized as problems (too many in the wrong place), other people are valuing them (campaigning against badger culls,

feeding birds in urban parks, and keeping rats as pets). This demonstrates that “pest” is a subjective and context-dependent classification and not an inherent property.

Important differences emerge in the pest management problems and priorities of developed and developing countries, linked to the resources available to manage pest incursions and the vulnerability of production systems and human populations to the effects of pests. Some developing countries are battling biblical swarms of pests that decimate certain agricultural sectors and adversely affect human health in urban areas. National differences in pest occurrence also have ramifications for agricultural trade, as the classification of national spaces as contaminated with particular pests restricts the legal trade of certain agricultural products.

Pest management is legislated at the regional, national, and international levels. At the international level, the Convention on Biological Diversity stipulates that signatories prevent the impact of nonnative species on native biodiversity, and the World Trade Organization sanitary and phytosanitary legislation stipulates that member states inform the international community of the presence of certain notifiable pests. National-level policies operate as stand-alone pieces of species-by-species legislation, as a part of wider environmental or agricultural legislation or as a part of integrated biosecurity legislation. Agencies with pest management responsibilities undertake a variety of coordinating activities, including developing pest management strategies, maintaining inventories of pests and the extent of their incursions, and disseminating best practices.

Control responses are determined according to the accessed level of threat a pest poses and the costs and capacity of human interference to effect change. The aim may be to prevent a pest’s spread, to reduce its negative impacts, or to achieve localized or long-term eradication. This requires the surveillance of areas for the presence or absence of pests, the selection and use of appropriate control methods, and any follow-up or monitoring work to prevent pest reestablishment. Integrated pest management (IPM) is the most well-known holistic approach, dominating the field of pest management for the past 35 years. Rather than

Source: Stephen Ausmus, ARS, U.S. Department of Agriculture.

simply considering treatment options, IPM focuses on why a system is susceptible to pests and collects information on the pests' processes of range extension (linked to both dispersal modes and opportunities in host environments) for the sake of developing better management practices. IPM also integrates different types of pest control techniques, including chemical, biological, and mechanical control methods.

Chemical control methods include the use of insecticides, herbicides, and fungicides (the term *pesticides* itself subsumes organic, inorganic, chemical, synthetic, and organo-synthetic products). Administred by hand, from ground machinery, or from the air, these include selective pesticides (species specific) and general (wide

spectrum) pesticides. It is in the use of chemical control methods that significant controversy surrounding pest management arises. These include health concerns to human populations through exposure to pesticides, through proximity to spraying on agricultural land, through residues on food, or through persistence and accumulation in the food chain. Environmental concerns include the direct effects of pesticide exposure on nontarget species, the reduction of available food and habitat, the cumulative poisoning of higher-level species, and the emergence of pesticide-resistant species.

Biological control methods include the release of a pest's natural enemies. There are many historic examples, particularly from the Antipodes,

of biological control agents becoming serious pests themselves. However, rigorous prerelease testing now accompanies biological control. Mechanical control methods involve barrier methods, traps or the hunting of larger animals, and frightening techniques such as recorded distress calls to deter birds. Cultural control methods refer to improved husbandry or management techniques to reduce a system's susceptibility to pests, including the use of trap crops, companion planting, and the avoidance of monoculture planting. These form an important part of IPM and organic farming. Other pest control techniques include varietal control methods, using pest resistance, including genetically engineered crop cultivars, and interference methods, such as the release of sterile males.

Within physical and human geography, pest management receives divergent attention, with little collaboration or conversation across a "realist" divide. Physical geographers contribute to the development of monitoring and management tools and to mapping and predicting pest invasion dynamics using retrospective and predictive computer modeling. In contrast, human geographers are occupied with critical explications of the underlying binary distinction between pest and nonpest, its association to other binaries such as native/alien and nature/culture, and its spatial and temporal dimensions. Research has highlighted historically shifting cultural associations both to native landscapes and to "pests" themselves and issues surrounding public antipathy toward aspects of pest management. Geography's unique perspective is its spatial expertise, whether through the application of geographic information system (GIS) techniques to map pest spread or through the conceptualization of the spatial dimensions of species' belongings. The integration of human and physical research expertise would allow the discipline of geography to expand its contributions, particularly as the pressures of climate change come to demand a new paradigm in environmental management based on species' movement and flux.

PETROLEUM

Petroleum, "rock oil" or "oil from the earth" (from the Latin *petra*, "rock" or "stone," and *oleum*, "oil"), is a complex mixture of hydrocarbons and other organic compounds. As a technical term, *petroleum* refers to liquid crude oil as well as natural gas, viscous and solid forms (bitumen), and other petroleum products and possesses a large range of colors and consistencies. In ordinary language, petroleum refers specifically to *crude oil*. Scientists believe that crude oil (measured in barrels, abbreviated *bbls*) formed during the past 600 million years in the Earth from the remains of single-celled planktonic animals and plants in ancient seas and lakes. Over time, layers of mud, silt, and sand covered these remains, forming sedimentary rock over them. Geologic heat and pressure from this weight turned the biomass into crude oil and forced it into nearby porous rocks. Several geological elements have to be present for any kind of petroleum to form. These include source rocks that are rich in organic materials to generate petroleum, porous reservoir rocks (such as sandstone) to store the petroleum, and a nonporous trap, such as faults, anticlines, or salt domes, to prevent the petroleum from leaking away. These formations exist at varying depths (mostly between 150 and 7,600 meters [500–25,000 feet]) in the Earth's crust (beneath land as well as offshore). Even though petroleum occasionally reaches the surface through seepages, most of the time, expensive drilling and pumping technologies are necessary to find, extract, and collect it.

Petroleum has been known and used in numerous regions around the world for thousands of

years: People have used it to light lamps, for caulking and waterproofing, for medicinal purposes, or as a fire weapon. New extraction technology resulted from the pioneering work of Edwin Laurentine Drake, who in 1859 innovated the technology of drilling wells on Oil Creek in Pennsylvania (later known as Titusville) by driving down pipes to keep the drill hole from filling in and thereby providing access to deeper oil fields. Kerosene, a petroleum distillate, eventually replaced whale oil for lighting, but there was no large demand for oil until advanced refining techniques and technological inventions created new uses for petroleum. In particular, the invention of gasoline-powered automobiles in 1885 to 1886 by Gottlieb Wilhelm Daimler and Karl Friedrich Benz and their later mass production along assembly lines conceived by Henry Ford around 1913 to 1914 provoked new demand for petroleum as an engine lubricant, and consumers and companies alike pushed for further oil drilling. These dynamics also generated a growing demand for *gasoline*—originally a by-product of kerosene—to fuel new automobiles. This demand spurred research for new sources and pushed companies to establish extensive distribution networks of gas stations. Thus, petroleum rose to be the most important fossil fuel of the 20th century.

Once they extracted crude oil, investors had to temporarily store, refine, and transport it. They developed cylindrical tanks made from wood or steel to provide storage before shipment or refining. Various designs emerged, with special forms for volatile liquids and other products. (The high flammability of petroleum and its products has led to numerous fires, starting with the early extraction places in Pennsylvania.) Crude oil also has to go through various refining processes, including distillation, which separates the hydrocarbon components from each other and turns the crude oil into usable products. New uses are created regularly and are present (along with autos and engines) in our everyday life, from plastics to lubricants, dyes, drugs, and many synthetic materials. Production sites for these products are often located far away from both refineries and consumers, as it is generally cheaper to move crude oil than the refined product. Railroads were an important early means of transportation, and barges carried oil on inland waterways or along

coastal areas. Now supertankers that hold 100,000 to more than 2 million bbls make possible the global transport of oil. Increased maritime traffic puts stress especially on choke points such as the Suez and Panama Canals and the Bosphorus Strait, making them important geopolitical sites.

Oil extraction, production, and resale depend on both large businesses and national governments, creating multiple transnational linkages and friction points. The oil industry has produced numerous powerful global players. Among the best known is ExxonMobil. Its roots go back to 1863, when John D. Rockefeller joined an oil-refining business in Cleveland, which in 1870 became the Standard Oil Company, which controlled the refining of 90% to 95% of all oil in the United States by 1880. Nine trustees, including Rockefeller, created the Standard Oil Trust in 1882 by merging various companies engaged in producing, refining, and marketing oil. The company became the model of economic concentration and control and successfully expanded beyond national borders, making petroleum the primary source of energy around the world. In 1911, the enforcement of federal antitrust laws led to its dissolution. The units of the complex themselves became global giants, including Exxon, Mobil, Amoco, and others (and some of them have merged again in subsequent years).

The oil business started out as a private business venture, but World War I was a turning point, as the military depended on gasoline for its ships, tanks, trucks, and cars. The growing political importance of oil and its geopolitical implications made it a major factor in colonialism, and wars—including the two world wars—have been closely linked to questions of oil ownership and availability. Oil companies and national governments have therefore closely collaborated at home and in colonial settings, leading, for example, to British government support for the Anglo-Persian Oil Company shortly before World War I under the influence of Winston Churchill and the *Compagnie Française des Pétroles* (CFP), founded in 1924 and today known as Total.

After World War II, when submarine attacks showed the vulnerability of oil tankers, the U.S. government initiated further construction of pipelines (the Big Inch and the Little Inch, built between 1942 and 1943 by War Emergency Pipelines, Inc.,

Figure 1 Major petroleum-producing countries. Some, but not all, belong to the Organization of the Petroleum Exporting Countries (OPEC).

Source: Barney Warf.

Note: blue = OPEC members, red = non-OPEC oil-producing nations.

a consortium that included the largest oil companies), as the safest mode of transport to bring crude oil from the source to the refinery and to the consumer. Thus, the density of pipelines is especially high in the United States. As oil-producing countries and those with import demands are located in different regions of the world, supplementary transnational pipelines are currently being planned in response to functional and geopolitical needs.

As oil sources in Europe and the United States peaked, the discovery of large oil fields in the Middle East, Venezuela, Nigeria, and Russia created new global players with national economies largely dependent on petroleum income. In 1960, some of them, including Iran, Iraq, Kuwait, Saudi Arabia, and Venezuela, formed a cartel, the Organization of the Petroleum Exporting Countries (OPEC), to control oil prices and flow. OPEC influences global politics and economies, as highlighted in the oil crisis of 1973 to 1974. New global players have also created new geographies of distribution. The Black Sea has become particularly important for European energy security at the beginning of the 21st century. Several pipelines cross Russia and lead to the port of Novorossiysk on the Black Sea

or Supsa on Georgia's Black Sea coast. In efforts to reduce dependency on OPEC oil and bypass Russia, several actors, including U.S. and various European petroleum companies as well as Azerbaijan's State Oil Company, formed the Baku-Tbilisi-Ceyhan (BTC) Pipeline Company. Since 2006, the new pipeline has transported Caspian oil to the Turkish Mediterranean port of Ceyhan, where tankers pick up the oil and carry it to their destination. The creation of state-owned companies in Mexico, Venezuela, Russia, and Saudi Arabia; the expropriation of foreign oil holdings; and the nationalization of the oil industry have all limited access to the largest part of known oil reserves and added more players to the global oil economy.

The growing number of uses for petroleum and its products has transformed our environment. Highways and other streets built for cars crisscross continents, nations, and cities, allowing commuters to travel ever-greater distances between home and workplace; planes claim the airspace, and airports create new nodal spots on the outskirts of cities. Heating oil has allowed the construction of larger buildings in colder areas (i.e., structures that are largely independent, in terms of heating and cooling, of their environment) and thus the

Figure 2 The geography of petroleum consumption. The enormous demand for petroleum leads to significant imports in Europe, Japan, and North America.

Source: Barney Warf.

construction of cities in places where it would otherwise not have been possible. The increased burning of fossil fuels, and the increased creation of carbon dioxide, plays a big part in current global warming and the pollution of the environment, while oil leaks can harm the natural environment, whether they are caused by ship crashes or the spilling of gasoline in an everyday environment. Rising petroleum costs, global warming, the leading industrial country's dependence on foreign oil, and the impending peaking of oil (if it has not already occurred) have led to first steps in rethinking of energy sources, which, in turn, may lead us to transform our landscapes and built environment again.

The changing transnational economic petroleum networks create capital flows and accumulation that are accompanied by cultural transfers. Company logos are visible on billboards, service stations, refineries, and headquarters worldwide; architectural and urban ideas travel as companies send their planners around the world or hire local representatives who will implement their ideas. Similarly, in countries where oil is administered by the national government, the government uses the oil money to implement its ideas and concepts in the built and urban environments. Thus, petroleum from extraction to resale

has an impact on the environment locally and globally. Its networks are an expression of the interconnection of various political, economic, social, cultural, and even religious actors across the globe and across time.

PEUQUET, DONNA

Donna Jean Peuquet, professor of geography at the Pennsylvania State University (Penn State), is a renowned and distinguished scholar in the area of geographic representation, particularly in representing the dynamics of geographic phenomena.

She earned BA and MA degrees in geography from the State University of New York (SUNY) at Buffalo in 1968 and the University of Cincinnati in 1971, respectively. In 1977, she obtained her PhD in geography from the State University of New York at Buffalo. Prior to becoming a professor at Penn State, she held positions at the University of California at Santa Barbara; with the U.S. Geological Survey (USGS); in the department of geography, SUNY at Buffalo; and in the International Geographical Union.

Peuquet was awarded a John Simon Guggenheim Memorial Foundation Fellowship in 2000 to further her work in the representation of geographic knowledge. The title of this fellowship project was “A Cognitive Approach to Representing Geographic Knowledge.” This project primarily applied geovisualization to develop a cognitively informed application for knowledge discovery of large geographic databases. She also co-organized, with Barry Smith from the philosophy department of SUNY–Buffalo, an interdisciplinary workshop on “The Ontology of Fields,” which was sponsored by the National Center for Geographic Information and Analysis, in Bar Harbor, Maine, in June 1998. She is also a faculty member of the GeoVista Center, a research center at Penn State that aims to develop human-centered prototypes for scientists and decision makers. She has served as a member of the board of directors of and as lead representative to the University Consortium for Geographic Information Science. She is a member of the editorial board of the *International Journal of Geographical Information Science* and the International Society for Photogrammetry and Remote Sensing’s *Journal of Photogrammetry and Remote Sensing*.

Peuquet has been involved in a number of research projects from the National Science Foundation and the National Geospatial-Intelligence Agency, among other funding agencies. These research projects can be thought of as an effort to

advance the synergy between geographic databases and geovisualization for solving problems in areas such as crisis management and national security.

Peuquet has supervised approximately 26 PhD and master’s students. She has also published a number of articles on topics ranging from raster versus vector, geographic knowledge representation, and geographic databases to geovisualization. Her current research focuses on capturing the dynamics of geographic knowledge using multiagent systems. Recent research on geographic knowledge representation is often limited to representing a static view of the world, for example, by using ontology, a “semantic graph” that consists of concepts and relationships connecting the concepts. Such a representation can only capture “what is there” for the moment when the representation is generated. But real-world geographic knowledge is dynamic; a representation should be supported with a dynamic mechanism, such as a multiagent system, that can revise the existing representation as geographic phenomena change over time.

PHENOMENOLOGY

In the simplest terms, phenomenology is the study and description of human experience. As used by geographers, phenomenology gives attention to the environmental, spatial, and geographical aspects of human experiences, actions, situations, values, and meanings. For example, why are places important in human life, and can their essential lived qualities be identified? How do aspects of physical space—a pathway structure, for example—draw people together informally or

keep them apart? In what ways do human beings encounter the natural world experientially, and can these various modes of encounter be described in their lived fullness? How do the qualities of individuals, groups, cultures, and environments contribute to the range and modes of geographical experience? These are the kinds of research questions that a geographer drawing on phenomenology might ask.

History and Nature of Phenomenology

Phenomenology's principal founder, the German philosopher Edmund Husserl, argued that behind the shifting flux of human experience and awareness, there are certain invariant structures of cerebral consciousness, which he claimed a phenomenological method could clarify in a way that earlier philosophical traditions could not. Husserl viewed consciousness and its essential structures as a pure "region" separate from the lived realm of experience. His approach came to be known as *constitutive* or *transcendental phenomenology*.

Other philosophers, however, argued that Husserl's transcendental structures of consciousness were reductive existentially and could not accommodate the wide range of ways in which human beings live in, experience, and encounter the world in which they find themselves. In his 1927 book *Being and Time*, Martin Heidegger argued that consciousness is not distinct from but tightly intertwined with the world in which human beings find themselves. In his 1945 book *Phenomenology of Perception*, Maurice Merleau-Ponty claimed that an integral part of this intimate commingling of people and their worlds is what he called *body subject*—that is, the invisible web of bodily intention expressed through action that smoothly conjoins human actions and behaviors with the everyday world at hand. This "existential turn" by Heidegger and Merleau-Ponty marked a significant conceptual shift from Husserl's realm of pure intellectual consciousness to the realm of lived situations, experiences, and meanings. Because Heidegger and Merleau-Ponty emphasized the nature and qualities of human existence in its everyday typicality, their approach came to be known as *existential phenomenology*. Geographers have most often used this style of

phenomenology, since their focus most often is people's experiences and understandings of real-world environments, spaces, places, landscapes, regions, and so forth.

From this existential perspective, phenomenology can be defined as the examination, description, and interpretation of phenomena, by which is meant anything that humans can experience. Any situation, event, process, living thing, or object that a human being can touch, taste, smell, hear, see, feel, sense, know, recognize, intuit, or encounter is a potential focus for phenomenological study. There can be a phenomenology of weather, of landscape, of flora and fauna, of architecture, of the home, of journey, of travel, of tourism, of learning, of privacy, of community, of conflict, of gender, of sexuality, of less-abledness, and the like. The aim is to describe the phenomenon *in its own terms*—in other words, as it is: a thing, a living being, an experience, an action, a situation, or an event in the actual lives of actual human beings in actual times and places. The goal is not ideographic portrayal, however, but the discovery and explication of underlying, lived structures and the relationships shared by many particular lived instances of the phenomenon.

Premises of Existential Phenomenology

A first central premise of existential phenomenology is that if we are to understand ourselves as human beings, we must ground that understanding in a conception and language that arise from and return to human experience and meaning. There is no world "behind" the world of lived experience, and the researcher must be skeptical of any conceptual, ideological, or methodological system that transcribes human life and meaning into secondhand, reason-based accounts—for example, positivist accounts that translate the fullness and vitality of experience into tangible, quantifiable units or social-constructivist interpretations that assume all human meanings are socially and culturally afforded and derived.

A second central premise of existential phenomenology is that human experience, action, and awareness are always *intentional*—that is, they are necessarily directed toward and finding their significance in a world of continually shifting experience, action, and meaning. Human beings

are always aware of *something*, whether a thing, an idea, a feeling, an imagination, a person, an event, or something else. Intentionality is central to a phenomenological conception of human experience because it means that people are inescapably enmeshed in their world—what Heidegger identified as *Dasein*, or being-in-the-world.

The everyday lived structure through which the sense of being in the world expresses itself is termed the *life-world*—the everyday world of taken-for-grantedness to which, typically, people give no attention. In turn, the unquestioned acceptance of the life-world is called the *natural attitude*, and one phenomenological aim of geographers is to identify and depict the lived dimensions and dynamics of the life-world and the natural attitude, which always include geographical, environmental, and spatial aspects.

Early Phenomenological Work in Geography

Though foreshadowed by the earlier work of “humanist” geographers such as Clarence Glacken, William Kirk, David Lowenthal, and J. K. Wright, phenomenological work in geography first appeared in the early 1970s, when some geographers criticized the then dominant positivist approach, which emphasized a priori theory and measurable data. One phenomenological criticism was that the positivist perspective did not work well for aspects of human experience and meaning not readily quantifiable in some way—for example, place attachment or heightened encounters with the natural world. At the same time, an emerging focus on environmental perception and behavior within the positivist tradition in geography led to research dealing with people’s environmental images, attitudes, preferences, territorial identifications, and so forth. This concern with people’s “inner worlds” in relation to the “outer” environment became an important conceptual and methodological bridge for geographers seeking a more qualitative, interpretive approach to environmental behavior and experience, including the potential use of phenomenology.

Most notable among these “humanistic” geographers, as they were often called at the time, were Anne Buttimer, Edward Relph, and Yi-Fu Tuan, all of whom drew on phenomenological ideas and methods. In her 1974 book *Values in*

Geography, Buttimer emphasized the importance of a phenomenological approach for understanding the role of personal and professional values in determining, often unconsciously, geographical ideas, theories, and results. In turn, Tuan’s 1974 book *Topophilia* drew on phenomenological principles to explore the wide-ranging lived expressions of human attachment to place.

Of these early phenomenological works, Relph’s 1976 *Place and Placelessness* was perhaps the most significant, because he delineated a phenomenology of place that was simple to understand, versatile in its conceptual and applied possibilities, and resilient in its ability to deal with the complexity and ambiguities of place. Relph argued that the existential crux of place experience is *insideness*—in other words, the more deeply one (a person or group) feels oneself inside an environment, the more does that environment become, existentially, a place. The deepest experience of place attachment and identity is what Relph termed *existential insideness*—a situation where one feels so much at home and at ease in a place that one has no self-conscious recognition of its importance in one’s life, unless it changes in some way—for example, if one’s home and neighborhood is destroyed by a natural disaster. Relph identified and described several other modes of place insideness and its lived opposite, *outsideness*—a situation where the person or group feels separate or alienated from a place in some way.

Later researchers have often drawn on Relph’s conceptual structure of place because the various modes of insideness and outsideness provide a flexible conceptual means for distinguishing the lived experience of place from its material, objectivist qualities. In addition, these modes provide a way to keep sight of the existential fact that (a) the same physical place can evoke a wide range of contrasting experiences for different individuals and groups associated with that place and (b) the same physical place can, over time, evoke vastly different place experiences for that same individual or group.

Phenomenological Research Today

The range of current phenomenological work dealing with geographical and environmental themes is considerable. Two themes are highlighted here—*place* and *lived space*—to illustrate research

directions today. Because there are many different disciplines and professions interested in studying environmental and geographical topics phenomenologically, much of the work highlighted here is done not by geographers but by philosophers, sociologists, psychologists, designers, and others.

One continuing effort is phenomenological research on place, both broadly, in terms of philosophical implications, and specifically, in terms of phenomenologies of particular places and their associated place experiences. On the one hand, the philosophers Edward Casey, Jeff Malpas, Robert Mugerauer, and Ingrid Leman Stefanovic have all written book-length works demonstrating the foundational significance of place and emplacement for understanding human being-in-the-world. On the other hand, researchers like the sociologist Ray Oldenburg and the psychiatrist Mindy Fullilove have studied real-world situations ranging from so-called *third places*—that is, public establishments such as taverns and cafés, where people informally gather and socialize—to the devastation of African American neighborhoods in American cities due to urban renewal.

A second related phenomenological theme is *lived space*—a person or group's modes of living and being in relation to space and environment. One important aim, in part guided by Merleau-Ponty's work, is to better understand the role of body-subject in affording spatial and environmental actions, behaviors, and situations. In this regard, sociologist Chris Allen has explored visually impaired children's everyday body-in-space encounters with their home and urban environment, while philosopher Kay Toombs has considered how less-abled persons' loss of mobility leads to a dramatically different manner of relationship with the surrounding physical and human world. Yet again, the architect Juhani Pallasmaa has examined how modernist architecture has regularly reduced environmental and architectural experience to an abstract aesthetic grounded in visual appearance and how an invigorated architecture might widen the sphere of experience to incorporate all the senses as well as the feelings and bodily movement one encounters.

More broadly, phenomenological work on lived space gives attention to how spatial patterns and relationships set horizons to the dynamics of human action and place, particularly with regard

to sensuous encounter and physical passage. Space, in this sense, relates to whether physical and designable elements facilitate activity and liveliness or inactivity and dullness. There is phenomenological interest in a particular kind of place structure and situation in which the spatial-temporal regularity of individuals potentially coalesces into a larger environmental dynamic that both sustains and is sustained by an attachment to and sense of place—what the phenomenological geographer David Seamon has termed *place ballet*. The urban designer Ian Bentley and his colleagues have developed a design and planning approach for creating what they call *responsive environments*—that is, places that, through their physical layout and design, provide users with a wide range of accessible choices within the immediate, walkable neighborhood. The design aim is to create permeable, high-density, and mixed-use urban districts that have a robust street life, a lively place ballet, and a vital sense of identity and community.

Criticisms of Phenomenological Geography

Since the early 1990s, phenomenological research in geography has been overshadowed by the more dominant conceptual approaches of postmodernist, poststructuralist, and critical geographies. Several recent histories of geographic thought suggest that the use of phenomenology by geographers largely ended by the late 1980s. This claim, however, is incorrect. In fact, the phenomenological tradition remains intact—that is, creatively alive—and emphatically distinct from the discipline's current “critical” emphasis, which some phenomenological geographers see as highly subjectivist, rhetorical, and arbitrary in approach and results.

Critique of phenomenological work today arises from both the academic “right” and the academic “left.” On the right are the positivists, who see phenomenology as imprecise, highly subjective, and without criteria for trustworthiness. On the left are the critical theorists of various persuasions, who distrust the phenomenological assumptions of orderly patterns, essential structures, and “things in themselves.” Currently, critique from the left dominates the evaluative discourse, and phenomenological work has been criticized variously by social constructivists, feminists, postmodernists,

and cultural-study theorists as (a) essentialist; (b) implicitly masculinist; (c) ignoring individual, social, and cultural variations and differences; (d) neglectful of power structures; and (e) assuming an ideological and ethical bias toward exclusionary, bounded places at the expense of cultural and place diversity, integration, and interrelations. Phenomenologists respond that their aims, methods of study, and conclusions are misinterpreted by these critics and that a progressive understanding of the importance of environmental and place experience for human wellbeing is essential in an increasingly placeless, mobile world of global connections, cyberspace, and virtual realities.

PHOSPHORUS CYCLE

Phosphorus (P) is an essential element for all life forms on Earth. Being a nonsubstitutable constituent of nucleoside phosphates (e.g., ADP [adenosine diphosphate], ATP [adenosine triphosphate]) and nucleic acids (e.g., DNA [deoxyribonucleic acid], RNA [ribonucleic acid]), phosphorus plays a vital role in biochemical reactions involving energy transfer and transcription of genetic information in living organisms. Moreover, phosphorus has a generally low bioavailability and is a nutrient that commonly limits the productivity of terrestrial, freshwater, and marine ecosystems. In contrast with carbon, nitrogen, and sulfur, which can exist in several oxidation states, phosphorus does not take part in reduction-oxidation reactions and is predominantly present in the +5 oxidation state as phosphate (PO_4^{-3}). On a

centennial timescale, global transfer of phosphorus occurs unidirectionally from the terrestrial system via river transport to the oceanic system. This entry provides an overview of the major phosphorus reservoirs and the rate of phosphorus exchange between these reservoirs in the global phosphorus cycle.

Containing only 0.03 Tg P (teragram of phosphorus), the atmosphere represents a very minor phosphorus reservoir globally. Compared with other major biogeochemical cycles, the cycling of phosphorus is unique in lacking a stable gaseous component. The majority of atmospheric phosphorus is adsorbed on particulate matter emitted from high-temperature fossil fuel combustion and sea spray. These particulate phosphori have a short residence time of approximately 3 days and are deposited rapidly on terrestrial land (3.1 Tg P/yr. [per year]) and surface ocean (0.6–1.6 Tg P/yr.). The global flux of phosphine gas (PH_3 , <0.04 Tg P/yr.) is not significant because of the lack of a favorable environment for microbial production and the great ease of PH_3 oxidation by air.

Phosphorus cannot be sequestered from the atmosphere by plants and microbes, unlike carbon and nitrogen. Apatite, with calcium and phosphate ions linked together in a hexagonal crystal structure, is the most abundant phosphorus mineral in the Earth's crust. The weathering of apatite rocks is the sole major source of phosphorus in the global phosphorus cycle, releasing 20 Tg P annually to the soil. Global soils in the top 60 cm (centimeters) store a total of 2×10^5 Tg P, but a large proportion of phosphorus is adsorbed on iron and aluminum oxides and is thus not readily available for biota. Although the available phosphorus concentration in soil is low, internal recycling of phosphorus helps sustain the growth of terrestrial organisms, which have a phosphorus reservoir size of 2,600 to 3,000 Tg. Assimilation of phosphorus by land biota from soils roughly equals the return of phosphorus from biota to soil, with a flux of 63 to 200 Tg P/yr.

Rivers are a major conduit of phosphorus, connecting between the terrestrial and oceanic systems. About 90% of phosphorus transported by rivers (18–20 Tg P/yr.) is associated with the particulate fraction. Natural denudation and human-induced erosion of physically weathered materials account for one third and two thirds of

the riverine particulate phosphorus flux, respectively. Most of the particle-bound phosphorus enters the ocean and settles on the shallow continental shelf quickly, without participating in the biological cycle. Dissolution of phosphorus-containing minerals is very low in the alkaline and strongly buffered oceans, but some of the phosphorus adsorbed on particle surfaces can be remobilized in seawater with high ionic strength. Rivers also carry 1.0 to 1.8 Tg P in dissolved reactive form to surface oceans annually, providing a major phosphorus source for uptake by marine biota.

The upper 300 m (meters) of the surface ocean contains a total of 2,700 Tg P. Dissolved phosphorus concentration in this zone, particularly in the top 100 m, is negligibly small owing to effective phosphorus stripping by biotic uptake and subsequent sinking of detritus. The exchange of phosphorus between surface ocean and marine biota represents the largest flux between reservoirs in the global phosphorus cycle. Biota dominated by phytoplankton incorporate 1,042 Tg P/yr. from the surface of oceans, while more than 95% of the assimilated phosphorus (998 Tg P/yr.) is regenerated in surface waters through the decomposition of dead marine organisms. In spite of the large phosphorus fluxes, the oceanic biota phosphorus reservoir of 50 to 138 Tg is relatively small, indicating a fast turnover and a short phosphorus residence time (18 to 48 days) in marine organisms. Some biogenic particles sink to the deeper layer without being mineralized, exporting 44 Tg P/yr. out of the surface ocean.

Deep oceans of the world store a substantial amount of phosphorus, totalling 8.7×10^4 Tg. Because of the absence of light, and thus photosynthesis, little reactive phosphorus is incorporated into biota at depths greater than 300 m. Moreover, as most of the particulate phosphorus is solubilized by microbes, dissolved phosphorus concentration can be as high as 3 micrometers in seawater deeper than 1,000 m. Wind currents trigger an upwelling of nutrient-rich deepwater in some places and a downwelling of nutrient-poor surface water in some others, leading to an overall net phosphorus transport of 40 Tg/yr. from deep ocean to surface ocean. A small proportion of particulate materials in deep oceans eventually reaches the seabed and is buried in sediments, at the same time removing 3.4 Tg P/yr. from the world's oceans. As

the largest phosphorus reservoir on Earth, soils below 60 cm depth, unconsolidated sediments, and nonmineable rocks together contain 4×10^9 Tg P in particulate form. Over the geological timescale of 10^7 to 10^8 yrs., crustal rocks formed from phosphorus-containing marine sediments are uplifted and subject to weathering again, thereby completing the global phosphorus cycle.

Human activities also play a role in shaping the global phosphorus cycle. Mineable phosphate rocks of the world, mostly found in North America and tropical Africa, lock up a total of 1×10^4 to 2×10^4 Tg P. Mining of these rocks for use as agricultural fertilizer enhances phosphorus availability and releases 12 Tg P/yr. to the global soil reservoir. Excessive use of inorganic fertilizers leads to increased phosphorus loss through runoff and eutrophication of freshwater and estuarine ecosystems downstream, resulting in oxygen depletion in water bodies and large-scale death of aquatic organisms. While agricultural application of phosphorus fertilizers and domestic and industrial discharge of sewage can cause phosphorus enrichment in some localized ecosystems, anthropogenic phosphorus inputs at the current rates have limited effects on the global phosphorus cycle because of the much larger magnitude of land and ocean phosphorus reservoirs.

PHOTOCHEMICAL SMOG

Photochemical smog is a noxious mixture of pollutants formed in the presence of sunlight. It is very harmful to humans, animals, and plants. The ingredients required for the production of photochemical smog are oxides of nitrogen (NO_x), volatile organic compounds (VOCs), and sunlight. NO_x and VOCs are themselves harmful, but in the presence of sunlight, they are involved in a complex series of reactions that create other harmful substances. Industry and transportation sources contribute most of the precursor gases. Photochemical smog is, therefore, most prevalent in urban areas. Ground-level ozone (O_3), a secondary pollutant created by reactions between the precursor gases, is the main component of photochemical smog.

Nitric oxide (NO) is emitted when hydrocarbons such as gasoline, diesel fuels, or coal are burned. It is a by-product of incomplete combustion. Once emitted, NO quickly oxidizes to form nitrogen dioxide (NO_2), a toxic, foul-smelling gas that gives polluted air its brownish/yellow hue. Collectively, NO and NO_2 are called NO_x . Volatile organic compounds are hydrocarbons that evaporate readily at normal temperature and pressure. Thousands of compounds fall into this category, and sources include evaporated fumes from fuel in vehicles, fuel combustion, petroleum refining, and industrial and residential solvents such as paints and cleaning fluids.

In the presence of sunlight, NO_2 will dissociate, and further reactions with oxygen gas (O_2) lead to the formation of ozone (Reactions 1 and 2). However, ozone will also dissociate in the presence of sunlight and react with water vapor to form highly reactive hydroxyl radicals (HO) (Reaction 3). If VOCs are present, the hydroxyl radicals react with VOC to produce peroxy radicals (RO_2) (Reaction 4). The peroxy radicals further react with NO to produce NO_2 (Reaction 5), and the cycle continues to create O_3 . These are simplified representations of the reactions:

Early-morning smog over Quito, Ecuador, June 2005

Source: Courtesy of Mark Welford.

Compounds such as peroxyacetyl nitrates, or PAN ($\text{CH}_3\text{-CO-OO-NO}_2$), are also formed in the process. PANs are important because they are harmful, have relatively long lifetimes in cold temperatures, and therefore can be transported to other locations where they release NO_2 . Carbon monoxide (CO), which is another by-product of fossil fuel combustion, may also be involved in reactions to produce ground-level ozone.

NO_2 concentrations are highest during morning peak hour traffic, while ozone peaks near midday. VOCs are most prevalent in summer because of increased evaporation in warm temperatures. The creation of ozone is also more profuse in summer because of the increased intensity of the sun. Ozone is not created at night, due to the lack of sunlight. Photochemical smog, therefore, leads to poorest air quality episodes on summer days, though mixing with other pollutants such as particulate matter can cause poor air quality at any time.

Other Factors

Geography and meteorology play important roles in the accumulation of pollution during smog episodes. Some urban areas, such as Mexico City, Mexico, or Denver, Colorado, are partially surrounded by mountains, which restricts the air flow. This limits dispersion by prevailing winds, causing pollution to accumulate, often to dangerous levels. Meteorological phenomena such as temperature inversions also exacerbate smog episodes. Temperature inversions occur when the temperature aloft is higher than the temperature at ground level. This results in stable atmospheric conditions with restricted vertical airflow, allowing pollution to accumulate below the inversion cap. The location and topography of some cities, such as Los Angeles, are conducive to the formation of temperature inversions.

Long-range transport of pollutants also contributes to the formation of smog in locations

downwind of the sources of pollution. Ozone, PAN, and other pollutants can be carried thousands of kilometers through the atmosphere by prevailing winds. This increases pollution from local sources in the downwind locations and also pollution in rural areas.

Health Effects

Ozone, PAN, NO_x , and VOCs are toxic pollutants that are injurious to animal and plant life. They can cause damage to the respiratory tract, leading to lung inflammation, and can also irritate the eyes and skin. The effects of short-term exposure include irritation of the nose and throat, coughing, and painful breathing. Long-term exposure can decrease lung function, retard lung development in children, and lead to premature aging of the lungs. Some VOCs are known to be carcinogenic. Photochemical smog can exacerbate cardiopulmonary diseases and may lead to premature death. Children, the elderly, and patients with cardiopulmonary diseases are the most susceptible. In plants, these pollutants are known to cause foliage damage, inhibit plant growth, and reduce yield.

Air quality criteria, set by governments in many countries, help alert the population to dangerously high levels of pollutants. In Canada, the criteria for O_3 and NO_2 are 80 ppb (parts per billion) and 200 ppb, respectively, averaged over a 1-hour period. North American cities exceed their respective criteria periodically.

Reducing Photochemical Smog

Photochemical smog is a phenomenon of anthropogenic origin and can be reduced by curtailing emissions of the primary pollutants, NO_x and VOC. This can be achieved by reducing gasoline consumption with the use of more fuel-efficient engines or the use of nonhydrocarbon energy sources. Individuals may choose alternative means of transportation, such as public transit, walking, or cycling, and reduce energy consumption at home. Industries are encouraged to adopt cleaner technologies to reduce emissions. Overall, lower consumption coupled with alternative energy sources such as solar or wind energy would help lower emissions and reduce photochemical smog.

PHOTOGRAMMETRIC METHODS

The main purpose of photogrammetry is to define the quantitative parameters of objects using images taken by photographic or digital cameras. The typical output of photogrammetry is a map or three-dimensional (3D) model of some real object or scene. Photogrammetry is widely used to compile topographic maps of Earth's surface.

Photogrammetry is based on principles of stereometry—a branch of geometry that studies the projections of 3D objects into 2D space; in particular, photogrammetry deals with the appearance of real 3D objects in two overlapping photographs (image stereopair). The fundamental geometric principle used by photogrammetry is triangulation. By taking photographs from two (or more) different locations, so-called lines of sight can be developed from each camera to points on the object. These lines of sight are usually called projection rays owing to their optical and geometrical nature.

A standard approach to classifying photogrammetric methods is based on the relative location of a camera and objects during a photographic process: In terrestrial, or close-range, photogrammetry, the photographic camera and the objects are both placed on Earth's surface, and the camera is pointed horizontally (parallel to the ground surface), while in aerial photogrammetry, the

camera is above the object and is pointed vertically, toward the ground.

In close-range photogrammetry, the photographs are taken by terrestrial photographic cameras (phototheodolites), placed on nonmovable tripods to take pictures from the ground. As vertical aerial pictures are taken from moving platforms (aircraft and satellites), the cameras are specifically designed to take measurable photographs while the platform flies along the path. An aerial photographic camera is an assembly of high-precision optical lenses and mechanical, electrical, and electronic components. Aerial photographic cameras are designed to take pictures using panchromatic or color photographic films that can be as long as 120 meters, with picture frames as wide as 40 cm (centimeters; 23 cm $\times$ 23 cm is a typical size of a frame image). Apart from classical photographic films, modern image acquisition systems use different digital technologies and acquire imagery directly in digital form.

When obtaining vertical aerial photographs, the aircraft normally flies in a series of lines, called flight runs. Photos are taken in rapid succession looking straight down at the ground, often with a 60% overlap between adjacent photos. The overlap ensures total coverage along a flight line and also facilitates stereoscopic viewing. The distance the camera moves between exposures is called the air base. Sequences of photographs in one single flight run form a strip of overlapping images; several runs, in turn, compose a block (mosaic) of aerial photographs covering large areas.

Aerial photographs often contain imprinted information such as the date and time of image acquisition, camera focal length, flight altitude, and other data, allowing calculation of image scale and approximate tilt of the particular frame. Fiducial marks, usually imprinted alongside photographs, allow precise measurement using photogrammetric instruments.

The accuracy of photogrammetric measurements in photographs is described in terms of micrometers (μm). A standard stereocomparator (photogrammetric equipment used for precise measurement) records the coordinates of points in an image as accurately as 5 μm ; top-precision comparators target a 1- to 2- μm accuracy of image measurements.

Metric properties of a single aerial photograph are defined by the rules of geometric optics, where all projection rays coming from an object (the object plane, e.g., Earth's surface) intersect in one single point inside the lens (the focal point, or center of projection) and then hit the film (the focal plane). The distance from the center of projection (focal point) to the focal plane (the film) is called focal length f , while the distance from the center of projection toward Earth's surface is called the flying height above the ground (altitude), H .

Central-perspective projection defines the relative position and geometry of the objects depicted in an image. The appearance of an object depicted in an aerial photo depends on the relative location of the projection point (from which the photo was taken) and the position of the object, and the orientation of the photograph itself is relative to the object plane (Earth's surface). Photographs with optical axes that are tilted less than 3° off the vertical line are regarded as vertical. The scale of a vertical photograph is approximately uniform over the photograph and is equal to the ratio of the altitude and the focal length of the camera lens. Measuring distances and directions on vertical photos is therefore easier and more accurate, and in flat areas, the vertical photos can almost be used as a map. Oblique photographs are taken with the angle from the vertical deliberately set somewhere between 3° and 90° , with preset angles of 30° and 60° . The objects have a more familiar view, which resembles the view the observer would get from a high vantage point, such as a hill or the roof of a high building.

Since the scale of oblique photographs varies over the image frame, distances and directions are not true, and measurements on such pictures are heavily burdened with object displacements.

Single images allow defining of the planimetric (X , Y) coordinates of an object, whereas in stereophotogrammetry projection, rays from two overlapping images are mathematically intersected to produce the 3D coordinates (X , Y , Z) of the points of interest. To define the 3D coordinates of a point in the object's coordinate space, the images have to be oriented relative to a particular coordinate system on Earth. This is usually done by using ground control points, identified in images and on the ground. The coordinates of

ground control points on the surface are defined by classical geodetic surveying or precise GPS (global positioning system) measurements. Modern cameras are usually connected to navigational systems such as inertial measurement units and differential kinematic GPS, allowing continuous recording of spatial position and angular orientation of the camera during the flight; this significantly reduces the amount of fieldwork.

In technological terms of image processing, photogrammetry combines the following basic activities: image measurements, optical image transformations, calculations, and drawing. With the evolution of technology, photogrammetry used three methods of image processing: analog, analytical, and digital. The analog method uses optical-mechanical instruments in all stages: from the measurements in image and optical transformations to the drawing of the final product (a map or sketch). In analytical photogrammetry, all initial measurements are done mechanically, but calculations are made by computers. Digital photogrammetry is based entirely on the computational power of modern computers in all stages of photogrammetric image processing.

Applications and subfields of photogrammetry include topographic and thematic mapping, generation of digital elevation models, industrial (engineering) and architectural photogrammetry, medical imaging, surveillance, and reconnaissance.

PHOTOGRAPHY, GEOGRAPHY AND

For more than 150 years, geographical concerns have shaped photographic practices, and photographic technologies have nurtured and documented geographical pursuits. This complex, dynamic, and mutually influential relationship between geography and photography can be studied from historical, practical, and theoretical perspectives. In 1839, two, quite different, processes for making permanent images “from Nature” were announced. These early photographic technologies offered a new way of encountering the physical and human world. Louis Jacques Mandé Daguerre’s method of producing a unique image on a silver-coated copper plate and William Henry Fox Talbot’s paper-based negative-positive process were quickly harnessed to geographical purposes in the form of field observations, travel accounts, prints, book illustrations, and teaching aids—uses that have survived and become increasingly sophisticated in an age of geographic information systems (GIS) and digital imaging.

From the first mention of “taking photographic pictures” in Alexander von Humboldt’s *Cosmos* (1849) to Vaughan Cornish’s appreciation of landscape through photography of scenery (1946) to Denis Cosgrove’s analysis of the “One-World, Whole-Earth” images from the Apollo space mission (1994), photography has played a variety of roles in the data-gathering practices, ordering mechanisms, and myth-making processes by which people have come to know the world and situate themselves in it. When first introduced, photography’s ability to record, store, and disseminate information in visual form made it a natural complement to geography’s long-established emphasis on observation, description, and visualization.

Difficult, messy, and time-consuming processes did not stop the first photographers from carrying hundreds of pounds of equipment on the Grand Tour, up the Nile, and into the jungles of the Yucatan. Embraced as an accessory to travel and employed to produce “man-on-the-spot” accounts, photography presented the scientific traveller and the gentleman adventurer a way to bring the world home, in visual form, for contemplation or study,

Geography Lesson daguerreotype. In the 19th century, photography began to have enormous impacts on the popular sense of near and far, bringing distant worlds into the experience of large numbers of people.

enjoyment, or analysis. Quickly, the camera became an instrument for acquiring or disseminating geographical knowledge in military operations, boundary and geological surveys, topographical mapping, immigration programs, tourism promotion, and ethnographic investigations. Practiced by travelers, photography mediated the personal encounter with unfamiliar places and peoples; collected by armchair travelers, photographs served as surrogates for travel and a first-hand experience of places.

As photography became simpler, cameras got smaller, processing became commercially available, and images in full color became a reality; three forms of photography increasingly became an integral part of geographical pursuits: aerial photography, repeat photography, and photogrammetry. Employing established, standardized methods for producing and interpreting images, these applications embrace photographs

as scientific data to be read, measured, and manipulated in the process of studying cultural landscape remains, establishing spatial coordinates, or observing physical landscape change. Early on, photographers carried their cameras (and their portable darkrooms) to the top of hills and tall buildings in order to record landscape views. True aerial photography was first attempted in the mid 19th century by the French photographer, Nadar, who, in 1858, ascended to a height of several hundred meters in a captive balloon to obtain a photographic bird's-eye view of the Earth, from which he planned to produce an exact topographic map. Two years later, James Wallace Black produced a view of Boston—according to Oliver Wendell Holmes, “as the eagle and the wild goose see it”—from a balloon 1,200 feet in the air. Since then, vertical and oblique aerial photographic techniques have been used to inventory and map natural and human-made features on the surface of the Earth. Today, geographical applications of aerial photography continue and multiply in the form of contemporary satellite imagery.

Chronologically replicated photographic views of the same subject are used to demonstrate change over time by exploiting the camera's ability to create a photographic baseline against which development or decay can be measured. Geographers are familiar with this practice through scholarly rephotography projects as well as popular then-and-now comparisons.

Phototopography, or photogrammetry, is another form of data photography intended to convey specific geographical information in visual form. First used in the late 19th century for practical surveying purposes, this application of the camera to geographical endeavor produces data to be mapped, compared, or quantified. The production and interpretation of air photographs, while in many ways very much a cartographic endeavor, employ photographs in an effort to read surface characteristics and spatial relations.

Used more generally as a means of gathering geographical information, photography became an integral part of exploring expeditions and imperial administrations, opening distant or exotic regions to 19th-century European eyes. Photographers in London, Glasgow, and Paris documented the changing geographical face of urban renewal, just as a series of stereoscopic

views produced on both sides of the Atlantic celebrated urban development in newly settled areas of the New World. Similarly, various projects to inventory the native peoples of North America, India, and the British Empire were, in themselves, photographic investigations of cultural geographies as well as visual expressions of the 19th-century penchant for ordering and labeling.

Quickly absorbed into the pursuit of geographical knowledge, photographs have been called on to explore the physical nature and negotiate the social meaning(s) of water, rocks, and animals; snow and ice; and trees, forests, and prairies. Beyond their obvious use in fieldwork, mapping, lecturing, and publishing, photographs are increasingly attracting scholarly attention as a primary source for expressing, reflecting, and shaping the relationship of people to place. Even scientifically conceived photographs are now subjected to critical scrutiny for the layers of meaning beyond the visual facts presented in the images themselves. In the wake of recent theoretical writings on representation and the relationship between knowledge and power, historical and cultural geographers have turned their attention to the role of photographs in the geographical imagination. In their studies of the ways in which photographs construct, confirm, and contest notions of landscape and identity, they have contributed to recent work on the “visual turn” in the humanities and social sciences.

Now, as environmental degradation and global warming increasingly attract media, government, and public attention and occupy the research agendas of both physical and human geographers, spatial concerns and geographical concepts are being embraced by photographers and curators, incorporated into their artistic statements, elaborated in their catalog essays, and reconceptualized in visual terms in major exhibitions such as “Imaging a Shattering Earth: Contemporary Photography and the Environmental Debate.” Large-scale sites of ecological degradation caused by human invention—industrial complexes and mining sites, dried-up lakes and flooded watersheds, landfills and waste ponds—have attracted the attention of a cadre of eminent, environmentally committed photographers such as Edward Burtynsky, John Ganis, Peter Goin, David Hanson, Jonathan Long, and John Pfahl, who have been

instrumental in inserting discussions surrounding the stewardship of our planet into the rarefied world of fine art.

Photography is also a key component in the exhibitions and events, education, and outreach of organizations such as Worldchanging, dedicated to sustainability, and the Natural World Museum, which partners with the United Nations Environment Programme, through the Art for the Environment initiative, to promote environmental awareness, attitudes, and action across social, economic, and political spheres. Using aerial views and then-and-now comparisons, the rhetoric of such organizations depends heavily on the visualization of geographical concerns through photography.

At the same time that the work of geographers, curators, and photographers increasingly converges on scholarly issues of space and place, lavishly illustrated magazines, photography exhibitions, Web sites, and coffee-table books, from *National Geographic* to Yann Arthus-Bertrand's *Earth From the Air*, continue to foster a popular geographical agenda to see and know the world and continue to employ photographs as “windows” on a world beyond our doorstep. Perhaps the most obvious use of photographs as “windows” comes in teaching and learning, where lantern slides and 35-millimeter slides have been the mainstay of classroom instruction and conference presentations. Yet even as a major technological as well as pedagogical shift takes place as slides are replaced by digital images, slide projectors give way to data projectors, and textbooks give way to WebCT, photography remains an indispensable part of our understanding and study of geography.

PHYSICAL GEOGRAPHY, HISTORY OF

Physical geography has a history that spans several thousand years, which is often intertwined with developments in geography's other major field of study, human geography. Some of the first applications of knowledge involving physical geography occurred more than 4,000 yrs. (years) ago. The main purpose of these early investigations was to map the natural landscape and human settlements observed as explorers traveled to new lands. At this time, the Chinese, Egyptian, and Phoenician civilizations were beginning to explore the spaces and places within and around their homelands. The earliest evidence of such explorations comes from the archaeological discovery of a Babylonian clay tablet map that dates back to 2300 BC.

Early Greeks and Romans

The early Greeks were the first civilization to practice a form of physical geography that was more than just drawing the location of natural and human-made features on maps. The ancient

Greeks were also interested in the shape, size, and geometry of Earth. Aristotle hypothesized and logically demonstrated that Earth has a spherical shape. Evidence for this idea came from his observations of lunar eclipses. Lunar eclipses occur when Earth casts its circular shadow onto the moon's surface.

The first individual to accurately calculate the circumference of Earth was the Greek geographer Eratosthenes. Eratosthenes calculated the equatorial circumference to be 40,233 km (kilometers; 25,000 mi. [miles]) using simple geometric relationships. This calculation was unusually accurate, considering the primitive technology used. Measurements using advanced satellite technology have computed Earth's circumference to be 40,072 km (24,900 mi.).

Most of the Greek accomplishments in physical geography were passed on to the Romans. Military commanders and administrators used this information to help direct the expansion of the Roman Empire. The Romans also made several important contributions to human and physical geography. Strabo wrote an extensive 17-volume series, the *Geographica*. Strabo traveled widely across the Roman Empire, and *Geographica* records what he had observed and experienced from a geographical perspective.

During the 2nd century AD, Ptolemy made a number of important contributions. Ptolemy's publication *Geographike hyphesis*, or *Guide to Geography*, compiled and summarized much of the Greek and Roman geographic information accumulated at that time. Some of his other important contributions include the creation of three different methods for projecting Earth's surface on a map, the calculation of coordinate locations for some 8,000 places on Earth, and the development of the concepts of latitude and longitude.

Middle Ages to 1800

Little academic progress in geography occurred after the Roman period. For the most part, the Middle Ages (5th–13th centuries AD) were a time of intellectual stagnation in Europe. The Vikings of Scandinavia were the only group of people carrying out active exploration of new lands. In the Middle East, Arab academics began translating the works of Greek and Roman scholars, starting

in the 8th century, and exploring the physical and human geography of southwestern Asia and Africa. Some of the important Arab geographers include al-Idrisi, Ibn Battutah, and Ibn Khaldun. al-Idrisi is best known for his skill at making maps and for his work of descriptive geography *Kitab nuzhat al-mushtaq fi ikhtiraq al-afaq*, or *The Pleasure Excursion of One Who Is Eager to Traverse the Regions of the World*. Ibn Battutah and Ibn Khaldun are well known for writing about their extensive travels in North Africa and the Middle East. In China, academics were using sophisticated geometric techniques to produce high-quality maps of their homeland.

During the Renaissance (AD 1400–1600), numerous journeys of exploration were commissioned by a variety of nation-states in Europe. Most of these expeditions were financed because of the potential commercial returns from resource exploitation. These voyages also offered an opportunity for scientific investigation and discovery. Consequently, these explorations added many significant contributions toward understanding the physical geography of the Earth. Influential explorers of this period include Christopher Columbus, Vasco da Gama, Ferdinand Magellan, Jacques Cartier, Martin Frobisher, Sir Francis Drake, John and Sebastian Cabot, and John Davis.

The Renaissance was also a time of many technological inventions. Some of these discoveries were made to improve navigation across Earth's surface and to better the production of maps. In 1492, Martin Behaim created a spherical globe depicting the Earth in its true three-dimensional (3D) form. Behaim's invention was a significant advance over the 2D maps because it created a more realistic depiction of Earth's actual shape and surface configuration.

In the 17th century, Bernhardus Varenius published an important geographic reference titled *Geographia generalis* (*General Geography*, 1650). In this volume, Varenius used direct observations and primary measurements to present some new ideas concerning geographic knowledge. His work continued to be a standard geographic reference for about 100 yrs. Varenius also suggested that the discipline of geography could be subdivided into three distinct fields of knowledge. The first field examines the shape, dimensions, and motions

of Earth. The second field deals with the tides, the relationship of day length with latitude and time, climatic variations, and other variables that are influenced by the cyclical movements of Earth and the moon. Together, these two fields form the beginning of what is now called *physical geography*. The last field of geography examined distinct regions on Earth, studying the political, economic, cultural, and social behavior of people.

During the 18th century, the German philosopher Immanuel Kant proposed that human knowledge could be organized in three different ways. One way of organizing knowledge was to classify facts according to the type of objects studied. Accordingly, zoology studies animals, botany examines plants, and geology involves the investigation of rocks. The second way in which one can study things is according to a temporal dimension. This field of knowledge is called history. The last method of organizing knowledge involves understanding facts relative to spatial relationships. This observation elevated the importance of geography as a major form of scholarship. Kant also divided geography into a number of fields of knowledge. He recognized the following six branches: theological, mathematical, moral, political, commercial, and physical geography.

From 1800 to 1950

During the late 1700s and early 1800s, academics began questioning the belief that Earth's landscapes were the result of relatively recent catastrophic events. The prevailing view at that time was that Earth was created through supernatural means and had been affected by a series of catastrophic events such as the biblical Flood. The theory of uniformitarianism suggested that the landscape developed over long periods of time through a variety of slow natural processes. The ideas behind uniformitarianism originated with the academic work of the Scottish geologist James Hutton. In 1785, Hutton suggested at several meetings of the Royal Society of Edinburgh that Earth had a long past and that this history could be fully understood in terms of processes currently observed. For example, he suggested that deep-soil profiles were formed by the weathering of bedrock over tens of thousands of years.

Hutton's ideas did not gain significant support from the scientific community until the work of Charles Lyell. In the publication *Principles of Geology* (1830–1833), Lyell presented a variety of geologic evidence from England, France, Italy, and Spain to prove Hutton's ideas correct. The theory of uniformitarianism was also important in shaping the development of ideas in disciplines outside the geosciences. The work of Charles Darwin and Alfred Wallace on the origin of Earth's species extended the ideas of uniformitarianism into the biological sciences. The theory of evolution is based on the principle that the diversity seen in Earth's species can be explained by the uniform modification of genetic traits over long periods of time.

The 19th century saw the emergence of a number of societies interested in geographic issues in Europe and the United States. The first of these societies was established in Paris in 1821. The founding of geographical societies in Germany in 1828 and Britain in 1830 quickly followed. The American Geographical Society was formed in 1852, and by 1866, there were 18 established geographical societies worldwide. During the 19th century, many university chairs in geography were established, especially in areas of study that fall squarely in the realm of physical geography.

In 1836, at the University of Neuchâtel in Switzerland, Louis Agassiz began studying glaciers and their effect on Earth's landscape. From field observations of alpine glaciers in the Alps, Agassiz developed an excellent understanding of how glaciers modify the landscape. Four years later, Agassiz published the theory that a great Ice Age had once dominated the planet. This theory was based on his observations in the highlands of Scotland, where he saw the remnant effects of glaciers on the landscape. In 1846, Agassiz came to the United States and found evidence that past glaciation had also influenced the landscape of the North American continent.

In Germany, Alexander von Humboldt and Carl Ritter also made substantial contributions to physical geography. Humboldt's publication *Kosmos* (1844) examines the geology and physical geography of the Earth. This work is considered by many academics to be a milestone contribution to scholarship in physical geography. Ritter's work focused on the study of the connections

between humans and their natural environment. Furthermore, Ritter's ideas suggested that regional variations in the nature of the environment produced different outcomes in this relationship.

In 1847, George Perkins Marsh gave an address to the Agricultural Society of Rutland County, Vermont. The theme of this speech was that human activity was having a destructive impact on the landscape, mainly through deforestation and land conversion. This speech also became the foundation for his book *Man and Nature, or The Earth as Modified by Human Action*, first published in 1864. In this publication, Marsh explained more fully the environmental consequences of the unceasing development of the American frontier. Marsh's work marks the beginning of an important field of research in physical geography—the study of how human activities degrade the natural environment of the Earth.

Intellectual expansion in the late 19th century set the stage for the fracturing of physical geography into a number of major subfields in the early 20th century. In Russia, V. V. Dokuchaev and his associates established pedology and introduced the idea that spatial variations in soil type could be explained in relation to parent material, climate, and topographic factors. Wladimir Köppen suggested that one could classify Earth's local climates based on regional variations in temperature and precipitation. Research at the Meteorological Institute at Bergen, Norway, laid the groundwork for the development of meteorology and climatology as disciplines of study. The work of Frederic Clements and Henry Cowles led to elaborate theories of plant succession common to biogeography and ecology.

Late-19th-century contributions from W. M. Davis and G. K. Gilbert helped make geomorphology the dominant field of specialization for physical geographers over the next 100 yrs. Davisian cycles of erosion and the subsequent classification scheme of landscape development were in vogue with geomorphologists for about half a century. This success was mainly due to the fact that this theory could be applied to a variety of landscapes and required only simple descriptive data. Gilbert's alternative approach tried to use quantitative methods to determine the exact processes responsible for landscape evolution. This process-oriented approach to geomorphology did

not become popular until the 1950s because of its need for advanced numerical techniques.

The number of researchers in the various fields of physical geography increased considerably during the first three decades of the 20th century. These researchers helped develop physical geography mainly through basic data collection, the creation of classification schemes to organize the data collected, and the postulating of theories of operating processes through the use of inductive logic. Data collection included activities such as determining the elevation of land surfaces, the classification and description of landforms, the measurement of the volume of flow of rivers, the measurement of various phenomena associated with weather and climate, and the classification of climate, soils, organisms, biological communities, and ecosystems.

During the 1930s and 1940s, physical geography slid into steady decline in importance in the academic world. At the heart of this decline was the fact that the discipline was having problems attracting new students, with fresh ideas. Descriptive-based approaches to physical geography that were very popular in the late 19th and early 20th centuries had become tired and uninteresting. Physical geography needed a radical shift in philosophy to attract new scholars.

Twentieth Century: Second Half

Starting in about 1950, research in physical geography experienced a fundamental shift in philosophy. Physical geographers began adopting a different scientific approach. This approach relied on logical deductive reasoning, model building, experiments, and other quantitative techniques. This quantitative revolution was also associated with a change in the way physical geographers studied the Earth and its phenomena. Researchers now began investigating the operating processes rather than merely describing the facts associated with natural phenomena. Today, this quantitative approach is becoming even more common due to advances in software, computers, and other measurement technologies used in the field and in the laboratory to perform research.

The modeling of natural phenomena using a systems theory approach became an important component of many studies beginning in the early

1960s. Systems theory suggests that natural phenomena can be viewed as being composed of a number of parts that work together through some process to produce an outcome. The application of systems theory also allowed physical geographers to become more reductionist in their research approach without losing connection with larger systems such as Earth and its four interacting spheres (atmosphere, lithosphere, biosphere, and hydrosphere).

The growth of physical geography as a discipline exploded in the 1970s. It was now becoming common for departments of geography in the United States, Canada, Australia, New Zealand, and various European countries to have one or more faculty members specializing in climatology, geomorphology, biogeography, or hydrology. During the 1970s, remote sensing and geographic information systems (GIS) were established as valuable tools for research in physical geography. At first, these tools were mainly used to monitor Earth's surface, to collect descriptive data, or to generate maps. But this trend quickly became less important as researchers began using these technologies with spatial statistics and to build interactive models of systems.

In the last two decades of the 20th century, there was an important change in the purpose of investigation in physical geography. Because of mounting environmental problems, physical geographers moved away from theoretical studies. Instead, these scientists started applying knowledge common to their disciplines to find solutions to these problems. For instance, climatologists suggested that global warming was caused by human activities that result in the emission of greenhouse gases into the atmosphere. Biogeographers argued that losses of biodiversity were mainly due to the conversion of ecosystems to agricultural fields and urban land use. Geomorphologists identified the potential hazard associated with building human settlements near earthquake faults. Hydrologists suggested that a number of human activities were responsible for the pollution of rivers, lakes, and groundwater.

The 21st Century

Physical geography in the 21st century has been characterized by the following key developments.

First, advanced measurement technologies and information-processing capabilities are becoming more frequently used for gathering and processing data. As such, our planet is now being actively monitored by a number of satellites, each with an array of sensors for gathering information about the changing nature of Earth's atmosphere, biosphere, hydrosphere, and surface landscape. Furthermore, the vast amounts of data collected by these technologies no longer require sophisticated processing by supercomputers. Standard personal computers now suffice.

Human population growth and a steady rise in resource consumption per capita have drastically increased the number of environmental problems in need of action. Some of the more important problems include global warming, acid deposition, stratospheric ozone depletion, ocean acidification, natural land cover loss, biodiversity reduction, the introduction of exotic species, and the alteration of biogeochemical cycles. As explained earlier in this discussion, physical geographers are well prepared academically to examine these serious problems facing our planet.

Finally, collaborations between physical geographers and individuals from other natural and social science disciplines are becoming more common. This trend is being driven by the fact that single disciplines do not have all the answers required to tackle current complex environmental problems. Complete investigation of these problems often requires an economic or sociological perspective to explain why human activities create environmental degradation. Furthermore, these problems can be rectified only through economic or societal changes.

PICKLES, JOHN (1952–)

John Pickles currently holds the Earl N. Phillips Distinguished Chair of International Studies and Geography at the University of North Carolina, Chapel Hill, where he is chair of the department of geography. He has also held academic appointments at the universities of Kentucky, Minnesota, and West Virginia; at the Ohio State University; at the Pennsylvania State University (Penn State); and at Natal Pietermaritzburg and Trieste.

For the past 20 yrs. (years), two main strands of scholarship have been the hallmark of Pickles's research work. The first and perhaps most well-known aspect of Pickles's scholarship concerns critical geographic information systems (GIS) and, more recently, critical cartography. The publication of the groundbreaking edited collection *Ground Truth: The Social Implications of Geographical Information Systems* in 1995 contributed to a critical rethinking of the nature of GIS as a social technology imbued with power relations. Importantly, this work injected critical social theory into understandings of technologies of control, analysis, and surveillance. More

recently, this interest has been extended to the development of a critical cartography. This research strand has involved a series of contributions to a critical social theoretic understanding of mapping and cartography, most clearly represented in the 2004 book *A History of Spaces: Cartographic Reason, Mapping and the Geo-Coded World*. This interest in critical cartographies has led to an engagement with a group of scholars and community activists in the United States and Europe aiming to produce alternative mappings of contemporary society through the Counter-Cartographies Collective.

The second area of Pickles's research and scholarship has focused on the development of a significant body of influential work on the political economies of power and development in South Africa and East-Central Europe. Much of this research has focused on the political economy of industrial and regional development and transformation through some of the most important societal transitions of the past 30 yrs.: apartheid and postapartheid in South Africa and transitions from state socialism in East-Central Europe. The work on industrial development and spatial power under late apartheid grew out of earlier PhD studies in South Africa. Part of this work focused on the emergence of Bantustan industrial production and inward investment from Taiwan, as the South African economy internationalized and as investors sought ways of overcoming the quota constraints on trade in the global apparel industry.

Since the late 1980s, following a series of bilateral U.S.-Bulgarian research exchange visits, Pickles's focus on industrial transformation, societal change, and power has resulted in a body of work on the globalization of the apparel industry in East-Central Europe. Seeking to explore the uneven integration and consequences of globalization and European integration in peripheral regions across that region, this work focused mostly on the transformation of peripheral regional economies through integration into global circuits of apparel production and export and the articulation between global commodity production and local societal forms, including ethnicity. More recently, these interests have been extended to consider the changing global economic geographies of apparel production following the end of quota-constrained trade in 2005.

There are two main hallmarks of Pickles's scholarship. The first is theoretical. Since his doctoral studies at Penn State in geography and philosophy, Pickles's work has involved a deep-seated engagement with critical social theory to try to understand the connections between space and power. This has been developed through his earlier work on phenomenology and spatiality (*Phenomenology, Science, and Geography*, 1985) and more recent work influenced by Marxist and post-Marxist social theory, from regulation theory to the ideas of Gilles Deleuze and Félix Guattari. The second hallmark is methodological. A characteristic of the majority of his scholarship is that it involves collaborative forms of research and engagement, described in Pickles and Smith (2007). From South Africa to the critical cartographies research group and engagements, to research on the globalization of apparel production in East-Central Europe, Pickles's work has involved a deep commitment to building collaborative networks not only to enhance understandings of material transformations but also to enable "local" scholars to engage in global circuits of knowledge production.

PILGRIMAGE

Throughout recorded history, the pilgrimage has been an important practice in most of the world's religions. It consists of an individual or a group leaving home and traveling to a sacred site that has a spiritual magnetism within their belief system. Pilgrims encounter both the core of the religion and their fellow believers in a new and enhanced way, before returning home somehow transformed by their journey. Such a site can be a unique center of divine presence (e.g., the Ka'bah in Mecca [Makkah]), a place that is the group's "most precious possession" (e.g., the Western Wall, in Jerusalem, of the temple destroyed in AD 70, for Jews), a place linked with primordial history (e.g., Varanasi [Benares] on the Ganges, in Uttar Pradesh, India), the tomb of a saint (e.g., the tombs of Saint Peter and Saint Paul in Rome for Christians or that of Husayn ibn 'Ali in Karbala, Iraq, for Shia Muslims), a place linked to a religion's founder (e.g., the holy places in Jerusalem for Christians), or a miraculous place of revelation or healings (e.g., Lourdes, France, for Catholics). To arrive at such a center, to engage in the rituals prescribed there, and to be in the "very place" and see, touch, and taste its sacred relics is experienced as desire fulfilled and as joy both in the object of the pilgrimage and in being part of the blessed group who have been so blessed to get there.

A few pilgrimage places have world renown (e.g., Varanasi, Jerusalem, Mecca, Rome), but the sacred sites that attract devotees are almost without number. In every region, there are sites drawing pilgrims: a holy well, a tomb, or some place where local tradition holds that there was an apparition. This site often provides a focal point for the region, and its annual ritual cycle establishes the fixed points in the locality's calendar (e.g., the apparition site of Tirano on the Swiss-Italian border). There are sites whose renown has spread farther afield and that have become national shrines (e.g., Thomas Becket's tomb in Canterbury, the destination of Chaucer's pilgrims in *The Canterbury Tales*). Last, there are international sites where pilgrimage activities have been responsible for the building of an infrastructure of roads, hostels, and support industries (e.g., the

routes from all over Western Europe terminating in Santiago de Compostella).

While a pilgrimage is undertaken as a response to a sacred demand (a command to travel to the place, the need to seek divine favor or make amends for sins, or the desire to be in proximity with the holy), it has all the effects on the societies involved that are associated with tourism, and it has often been an important factor in cultural and political developments. The Muslim pilgrimage to Mecca has been a key factor in creating a sense of Islam as a single transnational identity and community, with the pilgrims meeting one another as brothers and sisters. In the 11th century, Western Christians' desire for easier access to their holy places in Syria triggered the Crusades.

Pilgrimages, as an activity, usually belong to popular religion; it involves joining in group rituals such as processions at the site, touching sacred objects, wearing special clothes, and bringing home religious artifacts. As such, it often attracts criticism from a religion's intellectual corps—indeed, within Christianity, the rejection of pilgrimages as blasphemous frauds was one of the themes of the 16th-century Protestants (hence, pilgrimages are still frowned on by many who so identify themselves). Later, the rationalists saw pilgrimages as a form of primitive superstition that portrayed one place as more favored by the deity than another. Within many religions, the authorities seek to control pilgrimage activity, which often has the effect of removing the constraints of home and village among otherwise conservative people. Within Islam, however, such hesitations do not arise because the pilgrimage to Mecca (in its ideal form, the *hajj*, or the more convenient form, *'umrah*) is one of the Five Pillars of Islam and far more closely integral to the whole practice of the religion than pilgrimages in other religions.

Recent decades have seen a revival of interest in pilgrimages both in practice and among scholars. Many religions have found that modern transport has made pilgrimages far more easily undertaken, while within Christianity, a growing appreciation of the role of ritual and action in a community's life has led to a rediscovery of pilgrimage as an activity. Equally, many Western forms of Christianity are now quite happy to use

Holy Mecca in Saudi Arabia. An important practice in most of the world's religions, a pilgrimage consists of an individual or group leaving home and traveling to a sacred site, such as the Holy Mecca, which has a spiritual magnetism within the belief system.

pilgrimage—with its implication of life being an open journey that has not yet reached a destination—as a metaphor for the spiritual life. From another perspective, the advent of mass tourism has blurred the distinction between the tourist and the pilgrim—many tours take in religious sites en route—while there is also a secularized pilgrimage element in many tourist programs that include visits to significant sites (e.g., battlefields) or that respond to people's desire to stand in and relate to the place of some major event (e.g., Ground Zero in New York City is emerging as such a site).

While in Western thought for much of the past five centuries, pilgrimage activity has been under

sustained assault, more recent years have seen a renewal of interest. Anthropologists and ethnologists study the phenomenon's implications for societies, while for those undertaking research on ritual and religion, this interest has moved from condemnation of the practice as superstition or a mark of primitive belief to seeing it as providing an insight into religious consciousness and how rituals shape societies. Among geographers, there have been studies aimed at distinguishing pilgrims from other travelers such as tourists.

PLACE

The idea of place is at once simple and yet very enigmatic. The term is used daily in the English-speaking world, and it is hard to get beyond the commonsense level, in which most people think of it as any meaningful location. It has become a significant theme in many disciplines, but human geography has long claimed place as a central concept, although even among geographers there is little agreement about the meaning of the term and how it should be used in scholarly discourse.

Before the mid 1960s, the central word used in geography to identify areas was *region* rather than *place*. Academic geography came to be dominated by a search for similarity, generality, and pattern, often referred to as *spatial science*. But the concept of place refused to go away, becoming intertwined in a debate over its relationships with space. Space became associated with objectivist theories and place with subjectivist theories. The two terms increasingly became seen as representing alternative conceptions of spatiality (how space/place enters into human lives and social arrangements) rather than as inherently or internally related to each other. The scholarship privileging space has often been referred to as a social constructionist (building) approach, whereby a portion of space becomes a place only when humans invest meaning in it. The latter body of scholarship is based on the premises that before all else, every person is a being in the world and that human conceptions of space, time, and place must begin with our own physical constitution as an embodied being with certain corporal orientations and sensory capacities. From this perspective, humans cannot construct anything without being first in a place; that is, they must dwell somewhere.

Building Perspectives

This position has been espoused by geographers informed by Marxism, phenomenology, feminism, and critical social and cultural theory, who had become disenchanted with the lack of concern with social issues in spatial science and the way in which its proponents ignored the production of place by capital and global forces. To Marxist geographers, the differential impacts of capitalism were feeding the exclusive forces of bigotry and nationalism, as exemplified by conflicts in many parts of the world. Place thus had negative connotations. Critical cultural geographers began to use the concept of place to reveal the connection between place, meaning, and power. Place had to be understood in terms of social and cultural conflict, and once “places” were established, they became tools in the creation, maintenance, and transformation of relations of domination, oppression, and exploitation. Yet another approach spatialized ideas deriving from structuration theory to demonstrate that places were the outcomes of both larger structural concerns and individual and group action. Other studies demonstrated that the processes of economic competition were having varying effects across the globe, producing geographical difference rather than similarity. These studies led to the conception of place as “locale,” an objective arena for everyday action and face-to-face interaction and the subjective setting in which people develop and express themselves.

Dwelling Perspectives

During the 1970s, humanist geographers wanted to rehumanize human geography and felt that the way to do this was to focus on individual and group life-worlds in an attempt to recover people’s sense of place—that is, how different individuals and groups interpret and develop meaningful attachments to those specific areas where they live out their lives. Place, for these geographers, was seen as a universal and transhistorical part of the human experience, and it was not so much particular places that interested them but “place” as an idea and way of being in the world. This work also uses “home” as a metaphor for place; home is seen as the foundation of

human identity, the dwelling place of being. In most of this work, the concepts of oneness, rootedness, authenticity, and experience were given prominence. Subsequent accounts of place in this humanistic perspective have elaborated on these ideas, based on the principle that the social and the cultural are geographically constructed. Places are seen as requiring human agents, who in turn require specific places if they are to be the selves (with identities) they are in the process of becoming: There is no place without self and no self without place. Such places are woven together by movement (practice or performance) and by the network ties that produce places as changing constellations of human commitments, capacities, and strategies.

Place also has become key in the decentering of the authoritative form of knowledge in the world today—techno-science. Sociologists of knowledge, geographers, and anthropologists have argued that one common attribute of all knowledge is localness, that it is place based. Until recently, little attention has been paid to another problem, that of “knowing” local knowledge, but a number of anthropologists and geographers have begun to use place, and especially the concept of dwelling, to inform their work among indigenous peoples. Place making, in this work is a relational matter involving activities and experiences and focuses on “practice,” or “performance,” emphasizing embodiment. Furthermore, a number of indigenous scholars in different parts of the world have identified phenomenological approaches as being parallel to indigenous thinking, as both are based on the innate human experience of place. Indigenous peoples claim a cocreative relationship with their land, making places as much as places make them, with the body seen as the source of thinking, sensing, acting, and being and the basis of all relationships.

Connecting Building and Dwelling

Although disagreement remains over which conception of spatiality should be privileged, recent scholarship has addressed how space and place are inherently related to each other.

A number of these attempts have their roots in “building” approaches. Locale studies now

include a strong social dimension: Locales are inclusive and progressive sites of social life. This work recognizes both global connections and local specificity, which create a world of hybridized identities and hybridized domains of being and thought. Another approach sees the social production of the spaces within which social life takes place as the key to understanding how the abstract space of capitalism colonizes everyday life by means of both spatial practice and representations of space and how this is countered through new understandings built on a mixture of memories and residues of older place attachments and new practices. A third new way to overcome the space-place dualism has suggested that place is associational, with all manners of spaces and times woven together through the intersection of many encounters between people and things through time and space.

There are also integrative approaches that begin from a dwelling perspective. The formulation of the concept of the “geographical self,” the human subject who is oriented and situated in place, and the use of three related concepts—self, body, and landscape—are pertinent because they resonate with, and connect to, work being done on place from a building perspective. This formulation puts the emphasis on form: If the body is the form in which a creature is present as being-in-the-world, then the world of its being-in presents itself in the form of landscape. Another highly creative approach has examined trees as agents that co-constitute places and cultures in relationship with human agency. Using the concepts of dwelling and performance, this work has demonstrated at a practical level that these are fruitful ways of dealing with the richness and dynamism of places. Likewise, another agency-oriented approach argues that differences emerge in places through both place-based experiences and human agency and that such places are never separate but always parts of larger sets of places.

Conclusion

It is doubtful whether the proponents of one approach or another to place will ever agree. However, there is beginning to be some agreement that place involves both mental constructions and human agency. There are a number of

terms that are being used by scholars with very different philosophical positions, including self, body, landscape, practice, and performance. But like the term *place* itself, they are fraught with difficulty, being frequently equivocal, often ambiguous, sometimes evasive, often taken for granted, and always contested. Earlier key concepts involving a dwelling perspective (such as authenticity, involving a fixity, a rightness, a duration in place, a oneness and rootedness, where people and landscape become joined) have been replaced by the idea that places are ongoing productions, involving a human agency, and that they are fluid and multiscalar, complex and hybrid. Perhaps the focus in much recent work on the experiences of human beings as agents and on the practice or performance of place offers a practical way of resolving some of the ambiguities of the concept of place.

PLACE NAMES

Place names (or toponyms) are used to identify and differentiate geographic features, both human-made (e.g., countries, cities, and streets) and physically based (e.g., mountains, lakes, and rivers). Toponyms are systems of spatial reference and symbolic expression. They are one of the most fundamental ways in which people connect with places. Traditionally, geographers have classified and mapped names as artifacts; however, newer research emphasizes the politics of place naming.

Place Name as Spatial Reference

Place names facilitate the identification and physical navigation of the landscape, using a single word or series of words to distinguish one place from another. As part of the larger structure of language, toponyms permeate our daily vocabulary, both verbal and visual. They are found on road signs, advertising billboards, and addresses. Place names are critical to the use of nearly any kind of map, contributing to geographic knowledge and the development of a sense of place.

Although names are important points of reference, misunderstanding can result from conflicts in their use and spelling. The same name is sometimes applied to different places, and a place may have more than one name. Seeking greater uniformity in naming, particularly in response to growing electronic data demands, applied geographers have worked to standardize toponyms on maps and other publications. They have also established administrative procedures for dealing with new place names, name changes, and naming controversies.

Several countries, including the United States, have set up boards to review and rule on toponymic issues. The United Nations Group of Experts on Geographical Names (UNGEGN) assists in sharing the results of these national efforts and promoting the benefits of the standardization of international names. Despite the technical justifications for standardization, the process can lead to public disputes as authorities try to choose a single name for a feature.

Place Name as Symbol

Place names are also symbols to which people attach meaning and from which they draw identity. Names evoke powerful connotations, as became evident in Fayetteville, North Carolina, when residents along Anthrax Street demanded a name change. The street name had existed for several years but was reinterpreted in light of the tragedy of September 11, 2001, and bioterrorism fears. Its new name, Allegiance Avenue, offers a more patriotic association. The image-generating power of toponyms has long played a role in

place promotion—from the intentional misnaming of Greenland to the more contemporary practice of crafting idyllic-sounding monikers for subdivisions and apartment complexes.

Humans apply place names to create a sense of order and familiarity, frequently choosing names that reflect and reinforce the importance of their point of view. Even when time has erased other evidence, toponyms can provide insight into people's religious beliefs, ethnic origins, history, environmental perceptions, and political values. Interpreting such names requires reading their many layers of meaning. In 1916, the Canadian town of Berlin, Ontario, changed its name to Kitchener, honoring the British Secretary of War who died at the beginning of World War I. On one level, the naming reflected Canada's support of the Allied effort and the strengthening of its ties with England. On another level, it symbolized a nativist rewriting of the landscape and the anti-German hysteria sweeping across Canada.

Naming also represents a means of claiming or taking ownership of places, both materially and symbolically. In many world regions, a renaming of geographic features accompanied European colonial exploration. Explorers and mapmakers not only projected their Western values onto the landscape but also excluded and devalued the naming systems of the original inhabitants, in effect writing off native knowledge. The toponymic process sheds light on power relations—that is, which social groups have the authority to name—and the selective way in which naming privileges one worldview over another.

Place names are often characterized by a permanence that outlives their creators; however, they are not static symbols. Major global shifts frequently underlie the renaming of features—decolonization, the fall of communism, the rise of Islamic fundamentalism, recognition of minority rights, and so forth. In the United States, racial and ethnic groups have actively sought the removal of names containing racial slurs and the renaming of places to recognize their historical achievements. Hundreds of streets and schools bear the name of the civil rights leader Martin Luther King Jr. These names sometimes serve as arenas for debates about culture and identity, thus exposing the divisions within society.

Place Name Study

Geographers traditionally have collected, classified, and mapped toponyms as artifacts, using them to reconstruct the environmental and human history of places. Names provide clues about the direction and timing of human migrations, the location of settlements, indigenous perceptions of place, and the boundaries of vernacular regions. Naming patterns have also been used to reconstruct the original vegetation and land use of an area.

Newer approaches take a more contemporary focus and stress the politics of place naming. Rather than passive artifacts, toponyms are vehicles for reinforcing and challenging cultural and political ideologies. Studies have examined how government elites in countries such as Israel,

Germany, Romania, and the former Yugoslavia have used place names—particularly commemorative street names—to advance reinvented notions of national history and identity. Yet other scholars have examined naming as resistance; for example, marginalized groups such as the Maori of Aotearoa, New Zealand engage in toponymic struggles to establish their legitimacy within society. Mapping remains important to place name study; however, it is also necessary to study the naming process, the participants involved, and the very language used in referring to and debating toponyms.

PLACE PROMOTION

Place promotion is the development of advertisements for the purpose of attracting investment, tourism, and economic growth. These efforts can take on many forms and today are practiced by multiple actors, including but not limited to governments, chambers of commerce, tourism and convention bureaus, and economic development corporations and agencies. Examples of place promotion are found in most media today and reflect the specific goals of the groups advertising a place.

Historical Context

Efforts to promote places as tourism destinations and attract investment capital have been undertaken since the 1840s. Early place promotion efforts were begun by private firms seeking to develop the frontier regions. In particular, U.S. railroad companies were given government land grants to exploit. Encouraging settlers to homestead in order to create demand for railroad service entailed advertising campaigns extolling (and exaggerating) the virtues of farming the frontier. Railroads and resorts partnered to promote health tourism and the qualities of beaches in the late 1800s. The evolution of mass transit in the 1900s led to the earliest promotion of suburbs, invoking images of healthy homes away from industrial city cores. With current reliance on the automobile,

the selling of the suburb continues. Attracting industries and selling the advantages that one location might have over other places led to an era of place promotion combined with the provision of incentives and policies that continues today. These efforts were often antilabor, to lure industrial plants, and tax breaks were given to attract corporates.

As cities declined during the deindustrialization of Western Europe and North America, efforts to remake city images dominated. Bereft of their industrial economic base, cities turned toward services, shopping, and the creation of spectacles. Downtown shopping centers, sports arenas, and entertainment districts were incorporated in urban redevelopment projects in the 1960s and 1990s, a practice that continues today. Cities compete for assets such as conventions, professional sports franchises, and other markers of urban success in the 21st century. Culture also became vital to the image of cities, with Europe, Canada, and the United States overseeing efforts to develop science and education centers, aquariums, and museums focused on niche sports and local cultures to attract tourists and attention.

Academic Foci

Most research on place promotion can be classified roughly into two categories. The first is the application of marketing to places, and the second is debates about whether this is effective. An important question at the heart of these marketing efforts is whether a place can be marketed in the same way as a package of toilet paper or foodstuffs; many scholars argue that, with some adjustments, it can be. Others counter that the complexity of places requires the use of strategies specific to tourism or economic development. This research aims to improve the process of place promotion and its counterpart, place marketing, to provide cities and regions with the capacity to effectively lure tourism and investment.

The second category consists of critical perspectives on place promotion. Researchers working from this perspective argue that place promotion efforts are partial descriptions of cities and regions and thus leave out many voices of people who wish to have a stake in creating the

image of the city. They argue that elite business leaders and politicians go to great lengths to control the image of a city—a city’s “brand,” as it is referred to by practitioners. This implies an undemocratic process and the exclusion of other stakeholders’ perspectives on the place being promoted. Others point out that only select parts of places are highlighted in tourism and economic promotion efforts, often reflecting the racial and class divisions that all places contain.

Much of the most recent research still focuses on cities. Since the 1990s, much work has focused on cities in Eastern Europe, which faced economic hardship during the transition to a more market-oriented economy in many countries. Other emerging bodies of work examine the efforts of Chinese cities and regions, working under communist planning systems that are embracing more free market principles. Other research examines explicitly the processes of exclusion as target markets are created and reached, thus often leaving out minorities as target audiences for place promotion efforts.

PLANTATIONS

Plantations are assemblages of trees, shrubs, or plants deliberately established on an area of land. Plantations can also be understood as a system of agro-economic production. Plantations represent a dominant mode of industrial organization and social-ecological production in modern agriculture and forestry.

As an organizational form, the plantation has a significant colonial and postcolonial history. Between the 18th and early 20th centuries, tropical plantations were a primary form of colonial enterprise, organized around the cultivation of globally traded commodities, including sugarcane, bananas, coconuts, tea, cocoa, cotton, spices, and rubber. Different labor regimes became associated with the colonial plantation. In the Caribbean and the U.S. South, indentured and slave labor was widespread, while in the Netherlands East Indies and British Malaya, plantation labor regimes were based on organized transfers of people from South Asia. Labor control in colonial plantation development often involved a radical restructuring of preexisting social relations; this history, in many cases, continues to influence ethnic politics in contemporary societies.

Scholars have long made the linkage between plantations and the characteristics of “total institutions.” Political ecologists such as Nancy Peluso have analyzed colonial and postcolonial teak plantations in southeast Asia as an expression of state control and political-economic power. For James Scott, plantations can be understood as an emblematic form of agricultural “high modernism,” amenable to state rationalities of simplification, legibility, calculation, and control. The plantation as a social and economic technology has also been linked to state initiatives to suppress rural insurgencies, as in Malaysia and Myanmar.

While there are many organizational forms, large-scale plantations typically involve variations on the following characteristics: appropriation and control over land and property, a disciplined labor regime, corporatist or state-led management structures, the commodification and improvement of high-yielding planting material,

and the employment of industrial technology and finance capital. Not all plantations have been organized along logics of entrepreneurial capitalism and surplus reinvestment. The hacienda form of plantation development, which emerged in Latin America and the Philippines, was essentially a precapitalist form, involving the direction of surplus toward powerful oligarchic ruling families. Contemporary plantations typically involve state-led reforestation schemes or private sector firms integrated with global capital flows and markets.

The Great Depression led to a collapse in global plantation commodity prices through the 1930s. World War II, followed by anticolonial struggles, ended the age of colonial plantation regimes. In

some postcolonial countries, successful “land to the tiller” reforms were initiated. New global development institutions such as the Food and Agriculture Organization of the United Nations were closely involved in the establishment and promotion of plantations in the postwar period. New plantation boom crops, including oil palm, eucalyptus, acacia, teak, rubber, coconuts, sugarcane, soybeans, coffee, and cocoa, have radically reshaped tropical forest environments and have been associated with widespread deforestation. In Indonesia through the 1990s, the clearing of peat swamps for oil palm plantations, in association with El Niño climatic events, was identified as the primary source of uncontrolled forest fires, which blanketed south-east Asia in haze. Biofuels (including sugarcane,

corn, oil palm, and cassava) have emerged in the past decade as a new plantation boom crop linked to rising global energy prices. The convergence between agricultural and energy commodity markets is predicted to have negative implications for land use conversion, deforestation, and food security in many developing countries, although the rising prices of these agricultural commodities may also benefit some farmers.

In addition to transforming tropical and subtropical forest biodiversity, plantations have long been associated with serious land and resource conflicts with rural communities. The requirement of plantation companies for access to large areas of land, in combination with the legally insecure land rights held by many rural and indigenous communities, has led to problems of dispossession and

landlessness, as well as enclosure movements in many regions. At the same time, new social countermovements have emerged in resistance to plantation enclosures in the global South. The efforts behind community-based natural resource management systems have established improved legal recognition of local resource rights, although in many countries significant limitations remain on the ability of rural communities to actually claim legal rights over customary lands.

Many plantations in tropical countries involve the provision of state subsidies of various kinds, typically access to land through the granting of exclusive concessions at below-market rates. Some global forest policy institutions have argued against these subsidies, which promote the conversion of natural forest to plantations and

undermine the viability of smallholder farms. New market-based mechanisms of forest conservation, including programs of carbon sequestration and payments for ecosystem services (PES), are designed to increase the value of existing natural forests relative to the profits that can be made through forest conversion. In some cases, PES programs are being combined with community-based resource management systems to provide rural smallholders with more secure land rights and improved financial incentives for sustainable resource management.

Many rural communities have also engaged in the establishment of smallholder plantations, including the established smallholder traditions of cultivating “jungle rubber” in Indonesia. Rural people have also widely participated in the cultivation of various plantation boom crops, in some cases initiating a process of forest conversion, communal land privatization, and market-based dispossession. Initiatives in support of community-based resource management and forest-based sustainable livelihoods can thus at times be in tension with local and smallholder aspirations to engage with plantation markets and modernity.

There is significant controversy around the ecological effects of plantations, particularly fast-growing plantations of eucalyptus, pine, and acacia, and their putative effects on water and soil fertility. While these are complex scientific questions, the evidence supports a view that all trees access and use groundwater and soil resources and that fast-growing tree plantations use a corresponding amount of these resources. Balancing the ecological effects of plantations with other resource management objectives is considered to be a social and political question.

Plantations are not only established in the tropical or subtropical South. In the forest industries of North America, Scandinavia, New Zealand, Chile, and China, plantations of pine, poplar, spruce, and fir have widely replaced natural forest stands, leading to a decline in biodiversity as well as land conflicts with native, indigenous, or rural communities.

PLATE TECTONICS

Plate tectonics embraces the concepts of seafloor spreading (the creation of new oceanic crust at midoceanic ridges) and continental drift (the gradual movement of Earth's continents over geologic timescales) to provide a theory for the large-scale movements of Earth's lithosphere. This theory, together with the advent of remote imagery from satellite and aerial platforms, has led to a greater understanding of the large-scale geomorphology of Earth's crust. It has also helped us understand other aspects of physical geography, such as biogeography (which helps explain the distribution of biota across the globe), and emerging areas such as planetary geomorphology (which aids the identification of plate tectonic features on remote imagery of Mars). This entry outlines the theory of plate tectonics and its relevance to other physical geography phenomena.

Composition of the Earth

A section through Earth would reveal a rigid lithosphere that is 0 to 100 km (kilometers) thick. Although this layer behaves in a brittle-elastic manner, it can, under high loads and long time spans, deform as a plastic. The lithosphere is broken up into eight major and several minor plates, which are in motion with respect to each other and the underlying asthenosphere. The asthenosphere is a weaker mechanical layer, whose outermost portions contain some (less than 1%) partial

melt (material at $>1000^{\circ}\text{C}$). This behaves as a high-viscosity fluid. It is the interactions between the upper part of Earth's mantle (the asthenosphere) and the lithospheric plates that are significant for plate tectonics. Interaction between the plate boundaries and the resultant stresses within the plates determines to a large extent the distribution of seismic and volcanic activity, which is mainly concentrated at plate margins (Figure 1).

A tectonic or lithospheric plate is generally composed of continental or oceanic lithosphere from a few hundred to thousands of kilometers across. Plate thicknesses range from less than 15 km for young oceanic lithosphere to ~ 200 km for ancient continental lithosphere. The continental crust is composed predominantly of granitic rocks, which are made up of relatively lightweight minerals such as quartz and feldspar. Oceanic crust, however, is dominantly

composed of basaltic rock, which is denser and heavier.

Divergent (Constructive) Plate Boundaries

Divergent boundaries occur where two plates move apart from each other and tend to originate at triple junctions, which are sometimes believed to be associated with hotspots (Figure 2). At hotspots, extremely large convective cells bring vast quantities of hot asthenospheric material near the surface, weakening the lithosphere. Beneath the oceans, extensive submarine ridge systems represent divergent plate boundaries. Here, as the plates move apart, the space is filled with new crustal material that originates from the molten magma derived from below (seafloor spreading). It is at these locations that magnetic reversals were first identified from airborne geomagnetic surveys, which revealed a symmetrical pattern of magnetic bandings either side of the ridge crests. These bandings record reversals in Earth's magnetic field and provide data on the spatial and temporal spreading rate associated with the tectonic boundary. Only rarely are the ridges large enough to become emergent. Iceland

is one such example, situated over an upwelling mantle plume (hotspot) on the mid-Atlantic ridge system. Iceland is the only significant supramarine example of this 14,000- to 15,000-km-long ridge system, which runs from the Arctic Ocean to south of Africa. The volcanism associated with the ridge, in conjunction with the latitude (near the Arctic Circle), produces a unique environment where sudden volcanically induced melting of the ice sheets creates some of the most dramatic outburst floods on Earth.

In the continental lithosphere, divergent plate boundaries are responsible for the African rift system, generating rift basins and associated volcanic and seismic activity. Subsidence has generated the accommodation space for many of the lake systems, and associated warping of the crust has led to reorganization of the low-relief drainage systems associated with Lake Victoria, in some cases reversing them. During periods of enhanced plate activity, the increased volume of midoceanic ridges has been credited with displacing water in the oceanic basins, leading to sea-level rise and thus reducing potential carbon availability from weathering of the smaller exposed land masses, as well as increasing volcanic activity

and thus increasing the availability of greenhouse gases.

Convergent (Destructive/Active) Plate Boundaries

The nature of convergent plate boundaries depends mainly on the relative density, and thus buoyancy, of the lithosphere. Oceanic crust is considered denser (less buoyant) than continental crust. Where two similar densities meet (e.g., continent-to-continent collision, such as the Himalayas, or oceanic-to-oceanic merging, such as the Aleutian Island arc of Alaska), the crust will typically buckle and one plate will be subducted beneath the other. Where two different densities occur (oceanic and continental, e.g., the Andes of South America and the subducting Nazca plate), the denser oceanic plate will be subducted. These types of margins are commonly associated with explosive volcanism (Figure 2). This phenomenon is generally considered to be the result of the release of volatiles, predominantly water, as the subducted oceanic slab is heated at depth. This lowers the melting temperature of the surrounding mantle, producing magma, with the dissolved gases generating highly explosive eruptions.

Mountain ranges and volcanic chains are thus typical large-scale landforms associated with convergent plate boundaries. These types of margins are typically associated with dramatic relief. The Andes, for example, have a relief of up to 6 km and a corresponding offshore trench some 8 km deep, giving a total relief on the order of 14 km over a horizontal distance of some 750 km. This particular boundary is associated with large, megathrust earthquakes; in 1960, the largest recorded earthquake (magnitude 9.5) and tsunami were generated. The Peruvian coastline is one of the most tsunami-prone coastlines in the world.

Transform (Conservative) Plate Boundaries

Transform plate boundaries occur where there is oblique movement along a plate boundary. In these situations, convergent and transform boundaries may exist along the same plate boundary. This occurs along the western coast of the United States (convergent in the north, transform along

the San Andreas Fault in the south) and New Zealand (convergent in the North Island and transform along the Alpine fault in the South Island). Transform faults may also offset the crests of the midocean ridges of divergent plate boundaries. Where these transform faults occur, the plates are associated with stress buildup as a result of frictional forces. This stress will build to a critical threshold (the strain threshold of rocks on either side of the fault). The accumulated potential energy is released as strain. Ductile lower crust and mantle accumulate deformation gradually via shearing, but the brittle upper crust reacts by fracture, or instantaneous stress release, causing earthquakes to be common along the transform boundaries (see, e.g., the South Island of New Zealand or California in the United States).

The Driving Forces

The driving forces for plate tectonics are not clearly understood but are considered to be mostly related to gravity. When oceanic lithosphere forms at midocean ridges, it is initially less dense than the underlying asthenosphere. As it becomes cooler and older, it becomes denser. This is important for two reasons: (1) it generates an undersea topography where the elevation is greater at the midoceanic ridge and falls away with distance from the ridge as a result of the older, denser, and thicker oceanic lithosphere sinking into the asthenosphere and (2) the oldest and densest oceanic lithosphere is located at the subduction zones, farthest from the midoceanic ridge. Thus, gravity sliding (sometimes known as ridge push) from the topographic high of the ridge occurs. At the subduction zone, slab pull resulting from the weight of the descending slab is important.

In some regions, such as the Mediterranean, the slab pull, in combination with relative plate velocities, has led to a situation where the position of the subduction zone migrates regressively with time. In the Aegean Sea, the African plate is moving northeastward at 6 mm/a (millimeters per annum) and the Anatolian (Turkish) plate southwestward at 30 mm/a. Thus, the associated Hellenic subduction zone has to migrate away from both Europe and Turkey as long as these plate velocities are higher. In part of the oldest (50 million years ago), and thus densest, oceanic lithosphere of the

Mediterranean, the lithospheric slab drops almost vertically, leading to the “rollback” (regressive migration) of the subduction hinge. Subduction rollback is still active in the Central Mediterranean and has been used to explain the morphology of the Apennine Mountains of Italy.

Although gravitational forces are believed to be the strongest force driving plate motions, we also have to explain why some plates (e.g., the North American Plate and Eurasian plates) are moving but are not being subducted. This suggests that friction from large-scale convection currents in the upper mantle on the lithosphere may play a role. This may occur at subduction zones (slab suction) or away from these areas (basal drag). More controversially, some proponents have suggested that Earth’s rotation and the tidal friction of the moon may account for the westerly component of every plate’s motion.

PLAYAS

The word *playa* comes from Spanish and translates into English as “shore” or “beach.” As early as the late 1800s, however, the term *playa* was adopted for use in geomorphology in reference to the ephemeral lakes in the Great Basin of North America. To complicate things, *playa* is not the only name applied to these features, and names vary geographically, sometimes even at the local scale. Terms that are used more or less

synonymously with *playa* in North America include *playa lake*, *playa-lake basin*, *prairie pot-hole*, *buffalo wallow*, *rainwater basin*, *lagoon*, *salt pan*, *salt lake*, *alkali lake*, *bolson*, and *dry lake*. A variety of names come also from other parts of the world, including *vlor* (Southwest Africa), *sebka* (North Africa), *kewire* (Iran), *sabkha* (Middle East), *rei* (India), *praia* (India), *plage* (France), *pliazh* (Russia), *salar* (Chile), *boinka* (Australia), and *salina* (Spain and elsewhere). Though geographers and other Earth scientists have not yet completely agreed on a term, *playa* and *playa lake* are the most commonly used. Similarly, a wide range of definitions for *playa* exists in the literature, but one can reduce the myriad definitions to something relatively simple: an internally drained basin that is flat, barren, or sparsely vegetated, formed in prairie to desert environments and infrequently containing either freshwater or saline water. Though many have defined *playa* with a requisite diameter measuring hundreds of meters, many functioning *playas* are 100 m or less in diameter (see High Plains photo).

In North America, *playas* are ubiquitous on the High Plains of the Great Plains, but many also occur throughout the intermountain western region. Within the southern and central Great Plains, where *playas* are densest, estimated numbers range from about 25,000 to more than 40,000. Several origins have been proposed for these *playas*, but those most commonly cited are subsidence as a result of dissolution of subsurface salt or carbonate beds, the collapse of piping (conduits created by percolating water), eluviation (the downward movement of particles or dissolved solids), deflation, or various combinations of the preceding. Of these, deflation is frequently identifiable as having at least a partial role in *playa* development, in that on the downwind side of many *playas*, crescent-shaped dunes (lunettes) of clay- to sand-size material have accumulated (see lunette photo). Because of their characteristic location on the south to southeast side of the *playa* basin, lunettes in the High Plains likely developed during the last glaciation, when prevailing winds were from the north and northwest.

Playas are crucial to the ecosystems in which they occur. In the Great Plains, *playas* function as sources

of recharge to the High Plains aquifer, as wetland habitats for migratory waterfowl, as water sources for animals (wild and domesticated), as biogeographic islands for native wetland vegetation, as carbon sinks, and as sites for the breakdown of

agrochemicals. Throughout history, playas have served humankind as oases, first for the Paleoindians and subsequently for the early European settlers.

POINT PATTERN ANALYSIS

Point pattern analysis is considered a branch of spatial statistics involving the ability to analyze the spatial patterns of “events” that occur at a set of locations, with each event representing a single instance of the phenomenon of interest. Point patterns were initially studied in plant ecology 70 years ago, when researchers tried to describe and analyze the spatial distribution of plants. Point pattern analysis was gradually introduced into a wide range of fields such as archeology, epidemiology, astronomy, criminology, and so on. Meanwhile, the analysis received much interest in geography in the early 1960s during the quantitative revolution and was used and extended to examine settlement patterns, retail establishments, and spatial characteristics of the landscape such as drumlins, volcanic craters,

and others. In general, point pattern analysis is important for uncovering and studying the spatial processes underlying many types of point data.

To understand the processes that generate particular patterns, theoretic models are usually constructed. For instance, a simple theoretical model that has often been used is the complete spatial randomness (CSR) resulting from a homogeneous Poisson process over a study region. In this process, the probability of event occurrence for any area (A) follows a Poisson distribution with mean $\lambda|A|$, where λ is the fundamental property of a point process, representing the intensity or mean number of events per unit area. In other words, under CSR, events have an equal chance of occurring anywhere in the region, and event occurrence at one location is independent of that at any other location. Hence, under CSR, the study region is completely homogeneous in all respects, and no interaction exists between event occurrences.

One important aspect of point pattern analysis is to ascertain whether there is a trend for the events to exhibit a pattern, such as regularity or clustering, using CSR as the null. This issue involves the assessment of the departure of the event occurrence under study from CSR. If events tend to significantly concentrate or form groups different from those in CSR, the resulting pattern is considered clustering. On the other hand, if events are more dispersed or spread out than those in CSR, a regular pattern is formed. A straightforward method for the assessment is to explore the pattern by plotting and visualizing the point events. However, in general it is difficult to come to a conclusion purely based on a visual judgment, especially when the data set is large and other issues such as time or other relevant attributes or marks, such as type, size, or age, are considered. Therefore, various methods have been developed to explore and examine spatial point patterns.

Quadrat methods are the earliest methods used by plant ecologists to examine point patterns. This type of method is based on quadrats—well-defined frames of a certain shape, usually rectangular, although other shapes such as a square, circle, or hexagon can be used. The quadrats can be placed over the region randomly or contiguously. Then, the number of events falling into each quadrant is counted, and the intensity for a quadrant can be derived. Under CSR, a

quadrat with an area $|A|$ should follow a Poisson distribution with mean and variance equal to $\lambda|A|$, where λ is the intensity of the events. CSR also implies quadrat independence. Hence, Pearson's χ^2 goodness-of-fit test can be used to examine the pattern against CSR by comparing the observed and expected frequencies over all the quadrats.

Quadrat methods are highly dependent on how the quadrats are defined, and transforming points in a two-dimensional (2D) region into counts of 1D is subject to the risk of losing spatial information. Therefore, quadrat methods only give a general idea of areas with high and low intensity of event occurrence. An alternative is to use a kernel estimator to derive a smooth estimate of the intensity by moving a window of a fixed size over the region. This method transforms point data into a density surface for a specific phenomenon. The kernel intensity function can also be used to test for the overall clustering pattern as well as for location of local clusters.

The methods discussed above were developed mainly for identifying the first-order properties of a spatial point pattern by studying intensity variation in the study area. Other approaches focus on the distribution of interevent distances. One approach has been built on the nearest distances either between events (W) or from point to events (X), where a point is a randomly selected location in the study region. A simple way to examine a point pattern is to estimate the empirical cumulative probability distribution function $\hat{G}(w)$ of W , or $\hat{F}(x)$ of X . Under CSR, the average of the event-to-event distance, $\bar{w}$ approximates a normal distribution for large samples, and $\sum x_i^2 / \sum w_i^2$ follows an $F_{2n, 2n}$ distribution. Other test statistics using W and X are also possible.

In addition to the nearest distance, the commonly used K function takes into account a range of distances for examination. The K function, $K(h)$, is defined as the average of extra events within a distance h of a random event divided by the event intensity (λ). Under CSR, $K(h)$ would be equal to πh^2 , with the average number of events within a distance h of a randomly chosen event being $\lambda \pi h^2$. Under clustering, $K(h)$ is expected to be larger than πh^2 , and under regularity, it would be smaller than πh^2 . For formal testing, $\hat{K}(h)$ is usually transformed to

$$\hat{L}(h) = \sqrt{\frac{\hat{K}(h)}{\pi}} - h.$$

The assessment of the significance of the pattern can be achieved by simulation of CSR and establishing the confidence bounds for the transformed function $\hat{L}(h)$.

While a variety of methods have focused on investigating the general patterns of a region, attention has also been paid to examining local variation. A local method has been developed to quantify clustering at various scales by using $L(D)$, which is similar to the K function but is applied to each event. The local indicator of spatial association (LISA) has also been defined for local clustering examination.

POINT SOURCES OF POLLUTION

Point sources of pollution are individual, localized facilities that emit air and/or water pollution into the environment. Point sources can also emit thermal, light, and noise pollution. Point sources of air pollution are often also called stationary sources and are usually industrial facilities (e.g., coal-fired power plants, chemical plants, steel mills, paper mills, copper and aluminum smelters, oil refineries). A related category, area sources, refers to small, stationary sources of air pollution such as dry cleaners, bakeries, fast-food restaurants, home fireplaces, landfills, and gasoline stations. The other major source of air pollution is transportation, or mobile sources, which has accounted for a growing share of air pollution as increasingly strict standards have been implemented in many nations for stationary sources and as the automobile fleet size has increased. In the water pollution arena, the major point sources are publicly owned sewage treatment plants and industrial effluent dischargers. The other major sources of water pollution are nonpoint, diffuse sources such as runoff from agriculture, silviculture, storm water, and cities.

Point sources of pollution are usually regulated by government requirements to control emissions or effluents from smokestacks, pipes, vents, ditches, tunnels, or conduits, either by limiting the emission rate over a short time period or by controlling the total emissions into the ambient air or water. Permits are often issued that specify these requirements for the emission source (usually a private business), including the type of pollution being controlled, which could be one or more categories. For large industrial sources, these requirements can become complicated and expensive, involving dozens of point sources and many categories of air and water pollution. Since the 1980s, governments have increasingly turned to emissions trading systems to control point sources of pollution, especially in the United States. These approaches, such as emission offsets and “cap-and-trade” systems for sulfur dioxide and nitrogen oxides, are more cost-effective and flexible for industry. In the case of water pollution, effluent trading in watersheds even allows for trading between point and nonpoint sources.

In addition to the regulation of air pollution from individual point sources, atmospheric dispersion modeling is often required to determine the effects of individual sources on ambient air quality, particularly in urban areas. Such modeling requires mathematical simulation by computer programs to determine the atmospheric concentration of pollutants downwind from a range of sources. These models are important to the efforts of government air pollution agencies to design control strategies and plans. For water pollution, water quality simulation and waste load allocation models are used to similarly determine how multiple-point source dischargers can best meet ambient standards and total maximum daily load requirements.

POLES, NORTH AND SOUTH

The North Pole and the South Pole are defined by the intersection of the Earth's rotation axis with its surface. In a broader sense, the poles encompass all land and ocean at the high latitudes, where ice, sea ice, and snow are perennial.

Ice and snow are important components of Earth's climate system and are particularly sensitive to local and global climate change. Changes in snow cover and sea ice have immediate effects on land and ocean heating, the strength of major ocean currents, terrestrial and marine ecosystems,

and human activities. As stated in the Fourth Assessment of the International Panel on Climate Change (IPCC), “Warming of the climate is unequivocal, as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising global average sea level.” On this premise, the International Polar Year (IPY) was launched in March 2007, until March 2009. The program involves thousands of scientists from 63 nations, in more than 200 projects, to examine a wide range of physical, biological, and social research topics in the Arctic and Antarctic regions.

Unlike the South Pole, which lies on a continental land mass, the North Pole is located in the middle of the Arctic Ocean, surrounded by waters that are almost permanently covered with sea ice.

Continental ice sheets extend horizontally for hundreds to thousands of kilometers (km) and are 1 to 4 km in thickness. The two existing ice sheets over Greenland and Antarctica represent 3% of Earth’s total surface area and 11% of its land surface. They contain some 32 million km³ (cubic kilometers) of ice, equivalent to about 70 meters of sea-level change. During winter, large sections of the Arctic Ocean and Southern Ocean freeze into patches of sea ice.

Sea Ice

In the Arctic, sea ice coverage approximately doubles from 7 million km² (square kilometers) at the end of the summer melt season to 15 million km² at the peak of the winter. Around Antarctica, sea ice extent varies from 3 million km² during summer to 18 million km² at the height of winter.

Sea ice regimes and climate in high latitudes have changed during the past 30 yrs. (years). In the Arctic, sea ice has decreased markedly, reaching unprecedented low extents in the summer of 2007 (Figure 1). Scientists have calculated that ice extent in September 2007 was 50% lower than conditions from the 1950s to the 1970s. All models used in the Fourth Assessment Report of the IPCC indicate declining sea ice from 1953 to 2006. However, recent data show that the models underestimate the actual melting rate, leading to a conservative estimate of a seasonally icefree Arctic Ocean by 2030.

Antarctic sea ice extent has shown a slight increase in studies based on satellite mapping from 1979 to 2008, contrary to what the Arctic experiences (Figure 2). If the eastern part of Antarctica has seen very little change, the western part has witnessed significant declines for the past 25 yrs., and probably longer (measurements begin at the sub-Antarctic Island of Orcadas in 1901 and show a nearly monotonic warming trend). Monitoring and assessment of sea ice extent in this part of the world remain difficult because of the vastness and remoteness of the region.

Interestingly, the exact reasons behind these different trends in sea ice extent in the Arctic and around Antarctica are still mysterious and unresolved. Anomalous changes in atmospheric and oceanic circulations are currently being examined in both polar regions to explain them. In a letter published in *Nature* in 2009, Steig et al. argued for enhanced meridional flow—that is, more warm air reaches West Antarctica from farther north (i.e., from warmer, lower latitudes). This positive feedback mechanism (less sea ice, warmer water, rising air, lower pressure, and enhanced storminess) would explain the warming of the Antarctic continent over the past 50 yrs.

On average, the Arctic is warming twice as fast as the globe as a whole and the vast land masses of the region, at five times the global average. The amplified warming in the Arctic was attributed to positive feedback mechanisms that accelerate climate change, some likely triggered by the melting of sea ice, snow, and permafrost. A study by Gillet et al. in 2008, using an up-to-date gridded data set of land surface temperatures and climate model simulations, assessed the causes of the observed polar warming. They found that the observed changes in Arctic and the Antarctic temperatures are not consistent with internal climate variability or natural drivers alone and are directly attributable to human influence.

Greenland Ice Sheet

Representing almost 1/20 of the world’s ice, the ice locked atop Greenland covers 1.7 million km², for a total ice volume of 2.9 million km³. It has shed an average 150 billion metric tons more than

Figure 1 Arctic sea ice minimum extent in September 1982 and 2008. The red line indicates the median minimum extent of the ice cover for the period 1979 to 2000. This figure compares the Arctic sea ice extent in September for the years 1982 (the record maximum since 1979) and 2008. The ice extent was 7.5 million km² in 1982 and only 5.6 million km² in 2005 and down to 4.3 million km² in 2007. As has been observed in other recent years, the retreat of the ice cover was particularly pronounced along the Eurasian coast. Indeed, the retreat was so pronounced that at the end of the summers of 2005 and 2007, the Northern Sea Route across the top of Eurasia was completely ice free.

it gains in snow in winter over the past four summers (Figure 3). Although this is only a tiny fraction of its total ice volume, this shedding could weaken this survivor of the most recent ice age, 20,000 yrs. ago, when the climatic conditions were substantially different. It is very unlikely that the Greenland ice sheet will disappear in an instant or even a century, but the assumption that the total melting and collapse of such a large ice sheet takes millennia is being revised.

One reason for the revision is an unanticipated acceleration of outlet glaciers on the west and east coasts. The Jakobshavn Isbrae glacier on the west coast has doubled its speed from 5.7 to 12.6 km/yr. between 1992 and 2003, while the

Helheim and Kangerdlugssuaq glaciers started speeding up in 2002 and 2005, respectively. As the glaciers calve icebergs into the ocean, it relieves stress on the glaciers, allowing them to surge. One possible explanation lies in a warmer ocean bathing the coast, as data show a correlation between outlet glacier speeding up and warm ocean temperature. However, very little has been done to correlate water temperature and glacier movement so far.

Another area of interest is surface meltwater draining to the bottom of glaciers. Potentially, this could encourage movement and collapse by lubricating the interface between the basement and the glacier.

Change in annual mean sea ice
extent (% per decade)

Figure 2 Regional changes in Antarctic sea ice. In contrast to the Arctic (Figure 1), there are signs of a slight increase in the extent of annual mean sea ice in the Antarctic over the period from 1979 to 2005 (+1.2 % per decade) based on the NASA (National Aeronautics and Space Administration) team retrieval algorithm. There are far fewer observations of sea ice thickness for the Antarctic than for the Arctic because of the lack of submarine measurements. It is therefore not possible to detect any trends in Antarctic sea ice thickness over recent decades.

Figure 4 Antarctica, showing rates of surface elevation change derived from satellite radar-altimeter measurements

Sources: Hugo Ahlenius, cartographer and designer, UNEP/GRID-Arendal Maps and Graphics Library. Data from (corresponding to the numbers on the rectangles) (1) Rignot and Thomas (2002), (2) Ramillien et al. (2006), (3) Velicogna and Wahr (2006), (4) Chen et al. (2006), (5) Zwally et al. (2005), (6) Wingham et al. (2006), and (7) Rignot et al. (2007). Map retrieved and full source information available from http://www.unep.org/geo/geo_ice/graphics.asp.

Notes: The figure shows the rates at which the ice sheet mass was estimated to be changing based on radar-altimeter data (*black*), mass-budget calculations (*red*), and satellite gravity measurements (*blue*). Rectangles depict the time periods of observations (*horizontal*) and the upper and lower estimates of mass balance (*vertical*). Measurements by satellite techniques based on gravity indicate mass loss of ice at a rate of 138 ± 73 billion metric tons/yr. (per year) during 2002–2005, mostly from the West Antarctica Ice Sheet. However, two interpretations of satellite radar altimetry pointed to a much smaller loss of about 31 billion metric tons/yr. or a net gain of about 27 billion metric tons/yr.

Antarctica Ice Sheet

The Antarctic ice sheet covers 12.3 million km², for a total ice volume of 24.7 km³. Antarctica is also made of ice shelves—thick, floating slabs of freshwater ice extending from the coast. They cover an area almost as large as the Greenland ice sheet itself (1.5 million km²) but with a much lower ice volume (0.7 million km³).

Though there are uncertainties in the actual rate of mass loss, estimates indicate a recent shift to a net loss of Antarctic ice and suggest that the losses might be accelerating (Figure 4). Satellite missions over Antarctica are important as they

provide continuous monitoring of the ice sheets, allowing scientists to make predictions by finding evidence of trends in the data.

Using ERS and Envisat satellite missions from the European Space Agency, scientists identified new rifts (deep linear breaks in the ice) on the Wilkins Ice Shelf (WIS) on November 26, 2008 (Figure 5). The WIS is connected to two Antarctic islands by a strip of ice. That “ice bridge” has lost about 2,000 km² since the beginning of 2008, possibly leading to the opening of the ice bridge that has been preventing the ice shelf from disintegrating and breaking away from the Antarctic Peninsula. Six other

Figure 5 New rifts form on Antarctic ice shelf. Image acquired by Envisat's Advanced Synthetic Aperture Radar (ASAR) sensor. New rifts on the Wilkins Ice Shelf developed from August 10 to November 26, 2008. These rifts joined previously existing rifts (*blue dotted line*). The development of these rifts threatens to collapse the ice bridge that has been preventing the ice shelf from disintegrating and breaking away from the Antarctic Peninsula.

POLITICAL ECOLOGY

Political ecology is a relatively broad term that encompasses an interdisciplinary field, a theory, and a conceptual approach that focus on how power relations in society affect—and are affected by—the natural environment. In particular, political ecology explores the role of political powers, economic interests, societal norms, and emerging conflicts in environmental decision making. The approach centers on the notion that politics and environment are thoroughly connected on multiple scales and levels, as all access and control of natural resources are structured by power relations in human society. This affects all aspects of nature-society interaction and makes environmental issues on various levels inevitably political.

Political ecology offers analytical tools for a power- or knowledge-focused analysis applicable across theoretical, empirical, and disciplinary boundaries. The field emerged from a variety of disciplines over the past decades in a growing recognition of the complexity of the social influences surrounding environmental problems. It shares theoretical concepts with many other fields, such as political economy, cultural ecology, environmental sociology, anthropology, socialist ecology and Marxist theory, common property theory, green materialism, critical environmental history, ecofeminism and feminist development studies, rural land use and peasant studies, and postcolonial and critical development theory.

Themes and Goals in Current Research

Political ecology research consists of a diverse array of themes. These can loosely be categorized into four areas:

1. The first overarching goal of political ecology is to explore the reasons behind environmental degradation and marginalization, based on an understanding of the ecological situation as a result of its larger context in political economy. Political ecology provides a comprehensive analytical tool to reconceptualize three aspects of environmental problems. First, the *social construction* of environmental problems is analyzed. Environmental change is usually termed a problem or crisis where

it affects human interests adversely. Political ecology challenges the apparent causes of environmental problems and argues that most, if not all, environmental problems are not primarily ecological but in fact rather social problems. Prominent examples are land cover change and loss of biodiversity, soil erosion, air and water pollution, famines, floods, deforestation, land degradation, and desertification. Second, *uneven exposure* and *vulnerability* in environmental crises are analyzed. Environmental problems are often perceived by the socioeconomic dimensions of their impact on society, not by their ecological significance. This indicates underlying influences of power, access, and representation on the construction of environmental problems. Resource deprivation is not a uniform process. Environmental problems such as degradation and scarcity of resources receive much more attention when powerful elites are affected rather than vulnerable groups. Third, *unequal power relations* regarding resource access are analyzed.

2. The second goal of political ecology focuses on the social definition and political implementation of environmental conservation. This work aims at the social construction of conservation and nature itself. It challenges our understanding of concepts such as “nature,” “wilderness,” “natural resources,” “sustainable resource use,” and “aesthetic landscape,” asking how they are constructed and reinforced by powerful hegemonic structures in society and how they affect our regulation of land use and protected areas. The use and protection of natural environments are socially defined (e.g., “resource,” “sustainable use,” “scientific forestry,” “illegal harvesting,” “poaching,” “invasive logging”) and underlie the powerful paradigms that are derived from and reinforced by cultural practices and social norms.

3. The third goal is to understand the actors and interests of environmental conflict in the larger context of power struggles. Actors and their roles in conflict may be driven by gender, class, race, ethnicity, or other dynamics in society. Political and economic elites have historically aimed to justify resource use systems that were characterized by highly unequal access and user rights. Marginalized groups may be able to challenge the elite claims and seek ways to overcome the existing

power structures. Political ecology seeks to highlight the conflict over resources as much as it reveals the struggle over meaning. It raises questions such as “Whose environment?” and “Whose power or knowledge?” and analyzes the conflicting values, perceptions, knowledge, and discourses that reflect the underlying power relations.

4. The fourth goal of political ecology is to understand the social and political dynamics that emerge from changes in environmental conditions and regimes. This research analyzes the power dynamics of movements, shifts, or imbalances in resource distribution and ecological justice and provides insights that are often attributed to social change in a broader sense. At the same time, environmental movements, advocacy, and resistance are themselves subject to internal power forces that socially construct environmental narratives and their critiques.

These themes can be explored on multiple spatial and temporal scales with varying scope. Applications range from the relatively broadscales of sociocultural meaning (e.g., the Western concept of national parks) to short-framed political analyses (e.g., the passing of a new environmental law), from long-term research on sociopolitical issues (e.g., toxic waste disposal in marginalized regions) to social research on rural practices and livelihoods (e.g., customary access rights in rain forest communities).

Overall, one of the most central contributions of political ecology is its call for a heightened awareness of power inequalities and their impact on nature-society systems. The approach emphasizes the multilevel pervasiveness with which power relations shape and reinforce resource access and control, benefit distribution, and overall livelihood security. It offers a theoretical level of revisiting and questioning social assumptions to explore how concepts such as “sustainable use,” “natural resources,” or “equal access rights” become defined and reinforced by the dominant power structures in society.

Early Colonial and Ecological Critiques

Political ecology is commonly referred to as a new research field, but it has very old roots. Some early

European explorers and geographers criticized the racist hegemonic structures and growing inequalities as the underlying forces of environmental destruction and colonial exploitation, often based on their own observation. In his classic *Cosmos* (1858), the German geographer and world-renowned explorer Alexander von Humboldt coined the term *inequality of fortunes* and called for equal land use and employment opportunities between indigenous peoples and colonial powers. The French geographer Elisee Reclus criticized the colonial exploitation of his time even more openly in his work *The Earth: A Descriptive History* (1871). He suggested revolutionary political actions as a legitimate evolutionary mechanism to overcome inequities in hegemonic structures. In the late 19th and early 20th centuries, however, most human-environment research had become more formalized and was dominated by rather reductionist approaches that catered to the need of Eurocentric colonial expansion for cartography and physical geography.

Political ecology suggests a strong reference to ecology, a linkage that has been critiqued from various perspectives. Over time, ecological concepts became major influences on numerous fields, including health, development studies, environmental history, geography, economic processes, and cultural ecology. The study of ecological processes emerged in the mid 19th century, at a time when evolutionary research gained importance. Charles Darwin's evolution theory triggered a wave of debate across the social sciences to explore possible parallels to human processes. The evolutionary biologist and geographer Alfred Russel Wallace immediately opposed the emerging notions of social Darwinism and became an advocate of social justice and nonracist resource rights. At the core of the debate was the role of individual competition in evolutionary strategies as opposed to the role of social cooperation: While the "survival of the fittest" principle emphasized the ubiquitous importance of individual interests behind all societal decisions, the latter called for a balancing, ecosystem-level approach to better understand the full interactions between communities of organisms.

One early scholar who addressed the problematic implications of Darwin's theory for the social sciences was the Russian philosopher, geographer,

explorer, and activist Peter Alexeivich Kropotkin. He was arguably one of the first political ecologists. His pathbreaking work *Mutual Aid: A Factor in Evolution*, published in 1902, presented biological data that indicated that the central mechanism in natural selection is not competition but cooperation. In an often uncertain and difficult biophysical environment, it is cooperation among individuals that offers the best collective benefit to ensure survival. His findings challenged social Darwinist ideas, criticized the implicit reading of social hierarchies into the natural world, and thus repoliticized our thinking of human-environment processes.

Interdisciplinary Influences

Modern political ecology has emerged with multifaceted roots in various fields, most notably political economy and cultural ecology. The approaches of political ecology often have a historical component that shares concepts or focus with environmental history. Nevertheless, the term *political ecology* created a new unifying label for a research approach that had long been evolving in various academic disciplines, although concerned with large variations in concept, focus, and scale.

Political ecology shares with political economy the interest in the interaction between individuals, their material transactions in society, and the natural world. Political economy also assumes that society and nature are socially constructed to a significant degree but otherwise deemphasizes any natural processes or the environment per se. Environmental economics, on the contrary, has developed elaborate tools that seek to quantify environmental services and externalities. Although these have been contested, they help develop a larger economic framework but do not as adequately capture the underlying reasons, interests, and consequences of nature-society interactions as political economy helps grasp. The writings of Karl Marx experienced a revival through political ecology for their conceptual lens on the sociopolitical links between environmental degradation and social oppression, and this opened a new debate on the underlying structural concerns over economic production and resource depletion.

Neo-Marxism manifested itself as an influential theoretical contribution to early-stage political ecology from the late 1970s to the mid 1980s. It reflected the broader intellectual context at the time for new radical theories seeking to reconceptualize existing problems through new analytical lenses.

Political ecology is also significantly influenced by cultural ecology. Cultural ecology had emerged since the 1950s as a multidisciplinary approach across geography and anthropology to help understand how human societies affect and adapt to their local environments—how cultural practices and institutional arrangements evolve around resource use. Major works are associated with the American geographer Carl Sauer, who also pioneered the modern tradition of cultural geography in which environmental determinism was inverted into focusing on the role of humans in changing the landscape, not the other way around.

In the 1960s and early 1970s, cultural ecology attempted to explore the future of human populations and their material activities through ecologically based models such as energy flow modeling and system analysis. These models sought to explain adaptation and change as predictable outcomes of processes within the modeled closed ecosystems, but exactly because of this, they failed to acknowledge that the local cultural and ecological systems studied were in fact the result of larger sociopolitical dynamics on a global scale. From a political ecology perspective, this apolitical and homeostatic systems approach is the central conceptual flaw of cultural ecology.

Modern Reemergence Since the 1970s

Political ecology has been recognized as an academic field for only a few decades, and it continues to grow and be refined. The term *political ecology* was coined in the 1970s and received wider use in the 1980s and 1990s, when a growing circle of scholars started to identify themselves as political ecologists. Political ecologists come from various academic backgrounds, such as development studies, geography, political science, environmental studies, human ecology, anthropology, and environmental sociology.

Some of the earliest and most prominent scholars of the field in fact did not identify themselves as part of the movement and were rather situated by others in retrospect. This made the emergence of the field difficult to grasp and define, which continues until today.

The modern wave of political ecology can be described as a confluence of several sources of thought. New critiques in cultural ecology had increasingly opened up toward previously undertheorized sociopolitical determinants of human environment use. This development was embedded in a larger paradigmatic shift through the 1970s, with merging environmental and social movements. Escalating environmental degradation and livelihood crises in the developing countries, unforeseen local adversities from conservation efforts, and worldwide disagreement over possible solutions had made the growing global debate an increasingly politicized one. Voices for social justice increasingly joined the ecological concerns and raised the societal critique of global socioeconomic and political structures to a new level. Postcolonial resource use and industrial exploitation were increasingly identified as part of the problem. Political ecology formed as a critical response particularly to two popular notions at the time. First, it criticized neo-Malthusian beliefs that environmental destruction and global resource depletion were the result of overpopulation. Second, new political ecology voices challenged the globally favored technocratic practice of technology-based solutions that approached environmental problems as a merely technical matter, not as a complex social system.

The term *political ecology* emerged diffusely as a concept to grasp the new waves of environmentalist and social movements, in loose reference to political economy and cultural ecology. It first appeared in the writings of the journalist Alex Cockburn, the anthropologist Eric Wolf, and the environmental scholar Grahame Beakhurst. The first works in the academic realms of the field called for new concepts to explore the missing link between environment and society. They criticized the strong dominance of apolitical approaches in environmental research, the lack of postcolonial awareness in relation to it, and the limited application of alternative and radical thinking to conceptualize the growing threat of

resource depletion and overpopulation. These works were among the first in what was later termed *Third World political ecology*.

In the 1980s, the term *political ecology* was explored and enriched by key scholars such as Piers Blaikie, Michael Watts, and Suzanna Hecht. The research on power relations and human-environment interaction increased significantly, most prominently on land degradation issues, as book-length texts by Piers Blaikie and Harold Brookfield contributed significantly to the consolidation and formalization of the emerging research field.

Until the 1990s, the core focus of political ecology research remained in rural, agrarian, and Third World contexts. Political ecology slowly grew beyond its original core concern of Third World contexts and into a broadened, more theoretically consolidated and deepened school of thought that now increasingly addressed resource management and access to environmental resources, explored among others by Nancy Peluso and Karl Zimmerer. New streams complemented and diversified the field.

Critiques and New Directions

Political ecology has been critiqued on various levels over the decades. Its growth was rather iterative in nature due to constant exploration, elaboration, and reinvention of the field. Until today, a substantial part of its literature continues to be written in neighboring fields that form a heterogeneous and dynamic area of research rather than a coherent new field with clearly identified boundaries. Political ecology remains, in consequence, a fragmented and often incoherent field of research.

The disparate character of the field is often regarded as its central weakness. Some regard the disparate nature of the field as a weakening feature in need of a unifying voice and self-attributing coherence to move beyond the early stages of a new field. It has been argued that the term *political ecology* is too broad to capture all its different streams and nearly dissolves itself by trying to do so. It lacks consistent depth across the field, cannot determine its own conceptual boundaries, fails to agree on a coherent theoretical framework, and

does not offer a normatively derived framework to assess environmental processes or outcomes. For the same reasons, political ecology is also incapable of offering one big representative story or unified approach in response to current environmental debates.

Others, however, see the incongruent, heterogeneous nature of the field as possibly its greatest virtue because it reflects the ideas of political ecology at its very core. It pays tribute to its philosophical roots of pluralism, nonhierarchical discourse, and the teleological apprehension with which political ecology challenges all underlying connotations in the construction of knowledge and opinion for any political or academic discourse. Regardless, many critics agree to a certain extent that the emergence of the field mirrored an eclectic time of paradigmatic shifts in the social sciences, making way for the exuberant growth of nongoverned academic diversity and multidisciplinary.

Significant criticism emerged over what political ecology failed to address or addressed in research very late. Political ecology has been criticized for concentrating on land-centered research in its early phase and for failing to address air quality or water management sufficiently. The discipline also initially remained silent on gender issues and feminist geography approaches and needs to extend its theoretical tools to include research on the human body and health issues, urban contexts, and organizations and institutions in political-ecological conflicts. Others point out that although political ecology is centrally concerned with sociopolitical dynamics elsewhere, it failed to address the internal politics of the emerging field. In general, a wider shift toward discourse-oriented analyses in the social sciences since the 1990s has led to calls for more political ecology-based research on the power dynamics in the generation of knowledge, the social construction of inquiry, and teleological questions of motives and objectives in science and its possible merits and risks in technology-based applications. In the future, this opens up themes such as the expanding applications of geospatial methods and their construction of knowledges, shifting nature-society power relations through public participation tools, ecological modernization, and new debates on alternative political ecologies.

The critical debate on the future of political ecology thus indicates significant potential beyond the traditional realms of environment-related research. Ultimately, political ecology is not about nature. The initial references to ecology are increasingly contested, suggesting that political ecology needs to break away from a possibly outdated understanding of ecological concepts and dynamics. Some argue that nature-specific foci are in fact an early development stage of the discipline. The theoretical application of political ecology has started to widen beyond environmental issues and into the broader realms of sociopolitical research, ranging from postcolonial theory to urban planning and HIV/AIDS. Political ecology offers a multiscalar set of analytical tools to deconstruct social norms and unravel the underlying power structures in a wider context, and it is receiving growing attention from other society-related research.

POLITICAL ECONOMY

Political economy is a field of research and a body of theory concerned with the integrated study of political and economic decision making. It analyzes the behavior of political agents who make decisions in the presence of institutional and economic opportunities and constraints. Political economy has attracted growing interest within the social sciences, since the standard paradigm in economics of fully rational economic agents has failed to explain the continued prevalence of underdeveloped and even stagnating economies throughout the world. Similarly, political scientists have increasingly recognized the need to take economic constraints into account in analyzing political behavior. Political economy is currently one of the most intense fields of social science research. Many of the major recent theories in political economy consider geography to play a key role in understanding economic and political outcomes. This entry first describes the field of political economy and then provides an overview of some key areas of research: general geography, biogeography, disease environment, country size, natural resources, and trade.

Key Concepts in Political Economy

In the older literature—for instance, the works of Adam Smith, David Ricardo, Thomas Malthus, and Karl Marx—*political economy* referred to a more general analysis of how production was organized within states. Sometimes, political economy was even used as a synonym for “economics.” Some variants today are still Marxist inspired. The current use of the term *political economy* is, however, typically more narrowly confined to an interdisciplinary analysis of politics and economics. It is often indistinguishable from the field of public choice theory, associated with prominent scholars such as James Buchanan and Gordon Tullock. Public choice was for decades considered to be a “school of thought” on the side of mainstream economics, but as most of its key ideas (self-interested, optimizing political agents that act under institutional constraints) are now considered to be part of

standard economic theory, the field is usually referred to as political economy.

A typical feature of modern political economy models is to assume the presence of self-interested political agents who aim to remain in power and who try to maximize their own utility or the financial rewards for their own party or constituency. In this sense, political economy increasingly shares the fundamental assumptions made in microeconomics, where models are based on utility-maximizing individuals who are constrained by economic circumstances or strategic political limits rather than by morals or ideology. Political economy is further closely related to the field of institutional economics, which analyzes the importance of formal and informal rules of behavior for economic outcomes, such as norms of cooperation, private property rights, courts, parliamentary systems, and constitutions. Political economy is more focused on the interactions between political agents, their institutional framework, and economic constraints. In recent years, game theory has often been used for analyzing these interactions. As in economics, there has also been an increasing orientation toward empirical work.

The field reached a prominent position in social science with major publications such as Anthony Downs's economic theory of democracy (1957), and even more so with James Buchanan and Gordon Tullock's book *The Calculus of Consent* (1962). In that work, the authors analyze the voting systems in constitutional democracies and argue that there is an important trade-off to be made, in the sense that near-unanimity voting rules presumably have little external costs (few voters suffer damage from the chosen policy), whereas there are likely to be substantial decision-making costs before such a policy can be unanimously agreed on. Another key work from the same period is Mancur Olson's *The Logic of Collective Action*, published in 1965, which presents a theory of how small interest groups can obtain a disproportionately large influence over government policies. Recurring topics in the political economy literature over the years have been rent-seeking politics, interest group behavior, politically induced business cycles, the study of bureaucracy and corruption, and the impact of constitutions on economic outcomes.

General Geography

At least since antiquity, people have been aware that geographical conditions have a major impact on political and economic processes in society. In one of the first historical treatises ever written—*The Histories* by Herodotus—there are numerous references to the specific geography of the many places visited and how these conditions have affected societies. Most premodern philosophers and scholars also developed theories on the political impacts of geography, for instance, Plato, Machiavelli, and Montesquieu.

In modern times, a central work on the political economy of geographical conditions is Karl Wittfogel's book *Oriental Despotism*, published in 1957. Wittfogel developed his theory about "hydraulic empires," that is, how many of the early civilizations were founded on the need to control flooding and to construct irrigation facilities on the fertile river plains of the Nile, the Euphrates and the Tigris, the Indus, and the Yangtze and the Hwang Ho, the two major Chinese rivers. The sophistication and scale of these operations led to the emergence of centralized bureaucracies, economic specialization, social stratification, and the rule of autocrats who were often worshipped as gods. Tribute from unfree peasants or forced labor formed the basis of the wealth and power of a small ruling elite. According to the hydraulic hypothesis, there is a direct link between geography (fertile river plains in semiarid areas) and political economy. Many writers have proposed that a link can still be traced from these early conditions of statehood to more recent autocratic rule in Egypt, Iraq, and China. The hydraulic hypothesis has been criticized by scholars on Chinese history, who argue that the nature of despotic rule in ancient Egypt and Mesopotamia in fact had little in common with Chinese history. Furthermore, theory of a particular type of Oriental, riverine despotism misses the fact that the huge Indian subcontinent is fragmented and has not hosted major empires for long periods.

In the tradition of the hydraulic hypothesis, many scholars have contrasted the old riverine empires with the political economy of Europe. Europe has no large fertile river plains, and its general fragmented geography, with several

mountain ranges, peninsulas, large islands in the Mediterranean, indented coastlines, and hardwood forests, contributed to a continent that naturally featured a multitude of political core areas. By the same logic, geographically extensive empires were difficult to sustain in the longer run, which is one of the reasons why the earliest civilizations did not arise in Europe. This geographical fragmentation led to intense military and economic competition between smaller political units. The tax tribute needed to finance wars could be tolerated by the majority of the population only after the executive power had committed to limiting its power over its citizens. This in turn implied an economy that was more dynamic, open to new ideas, and fostered several “proto-capitalist” episodes even in preindustrial Europe.

This view of the benefits of a fragmented, competitive Europe is argued by some to be a “Eurocentric” analysis in that it does not give an accurate account of history. Europe has, for instance, hosted some very powerful political units, such as the Roman and Frankish empires, and its military competition has also been enormously costly in terms of capital and human lives. Some studies also indicate that living standards or levels of technological sophistication were not substantially higher in Europe before AD 1500 and that the source of European economic and political prominence is really to be found in the internal institutional and political changes that colonization brought about. The impact of colonization on European countries’ political economy was further quite diverse. In the Netherlands and in the United Kingdom, the inflow of revenue from the colonies strengthened mainly the merchant class, who in turn demanded more political power, a realignment of policy toward free trade, and strengthening of property rights. In Spain, however, the inflow of bullion from America led to inflation, an even more autocratic executive, increased government expropriation of private property, and eventually a bankrupt government.

Political Ecology

A very influential and more recent theory of the long-run political economy of the world is offered in Jared Diamond’s famous 1997 book *Guns,*

Germes, and Steel: The Fates of Human Societies. His basic argument is that regions experiencing an early transition to agriculture, civilization, and statehood gained a head start and an initial advantage over other regions that was still present when the race for colonies started around 1500. This longer experience of statehood explained why political units from Western Eurasia could colonize America, Africa, and large parts of Asia, which in turn shaped the broad contours of the international dispersion of wealth and power. Hence, to understand Western hegemony, one must understand why some areas adopted agriculture earlier than others. According to Diamond’s hypothesis, the main reason for an early transition is to be found in the greater access to suitable plants and animals for domestication in, for instance, the Middle East and along the Chinese rivers. The Americas also had independent centers of agricultural origin based on plant domestication in, for instance, the Andean highlands and Mexico, but the absence of suitable draught animals put substantial constraints on military technology, as well as on economic development. It also meant that the native population had not developed any resistance against the microbes (of animal origin) that the Spanish brought on their arrival, which led to the death of tens of millions of people from smallpox and other diseases.

Disease Environment

The geography of disease is another factor believed to have had a significant impact on colonial policy and hence on subsequent political and economic developments. According to the theory proposed by Daron Acemoglu, Simon Johnson, and James Robinson, the disease environment partly determined whether European colonists chose to settle and build European-style communities or resorted to unproductive extraction of natural and human resources. In tropical areas such as Western Africa, mortality among Europeans as a result of illnesses such as malaria and yellow fever prevented colonization of the continent for centuries. Instead, white merchants resorted to slave trading until the late 19th century. The colonization of Africa witnessed a

large-scale exploitation of its human and natural resources. Where the climate was more similar to that of Europe—as in the temperate “settler colonies” of South Africa, Australia, the United States, and Canada—institutions were installed that were based on private property rights and governments’ responsibility to an electorate. As a result, the political economy in these colonies acquired features similar to those of, for instance, the United Kingdom. In large parts of Africa, on the other hand, the extractive institutions created by the colonists prevail even now. According to the theory, the disease environment can thus partly explain the pattern of rent seeking, corruption, and patronage politics that still constitutes a major hindrance to African economic development.

Country Size

The size of political units has been an object of intense study among political philosophers since antiquity. Both Plato and Aristotle believed that the typical Greek city-state, with roughly 5,000 free men, was the ideal size of a political unit. Montesquieu also warned that large countries were more likely to host accumulated wealth, which could easily become the object of predatory struggles, and that socially optimal policies would be the exception since governments must devote all their energies to balancing numerous separate interests.

Country size should, however, in the long run be endogenously determined by geography as well as by institutional, economic, and military factors and events. Alberto Alesina and Enrico Spolaore proposed a theory where the optimal country size is determined through a trade-off between economies of scale in public goods provision, on the one hand, and preferences for heterogeneity in such goods, on the other. Large countries on average have a lower per capita cost of public goods such as defense, it was argued. Large countries, however, also contain a greater number of conflicting interests and groups. Their hypothesis further predicts that countries tend to be smaller under democratic and free trade regimes.

Alesina and Spolaore’s framework has been criticized for not being applicable to former

colonies, where borders often have not been the result of the type of rational calculations suggested above. Jeffrey Herbst argues that for Africa, colonial borders are often quite unnatural, crossing in the middle of ethnic as well as environmental zones. An important part of Africa’s political problems since independence stem from the fact that most countries are states without nations in the European sense. Still, Herbst argues that African borders also are an asset in governments’ state-making ambitions and in their attempts at broadcasting power from a core to a peripheral part of their territory.

Natural Resources

Empirical studies have repeatedly demonstrated that natural resource abundance has a significant negative effect on economic growth. This effect has become commonly known as the “curse of natural resources,” where natural resources are often defined as primary products, including oil, minerals, and agricultural products. One potential explanation for this curse is the “Dutch disease,” in which a booming natural resource sector draws labor away from the manufacturing sector and causes an appreciation of the real exchange rate, as occurred in the Netherlands after discovery of a large natural gas field in 1959. The negative effects on both the manufacturing sector and international trade are thought to be responsible for the poor growth performance of resource-rich countries in this case. Another potential problem associated with natural resource abundance is the reallocation of resources away from productive activities and toward rent seeking. Rent seeking can take many forms, from tariff protection and corruption to outright appropriation. In the extreme, the desire to control the rents from natural resources can lead to armed conflict and civil war. The primary result of increased rent-seeking activities is a decline in productivity, which in turn has a negative impact on economic growth.

The potential causes of such a “resource curse” are generally poor policies rather than natural resource abundance per se. Support for this claim can be found in a number of empirical studies that demonstrate that countries with sufficiently

strong institutions are able to escape the resource curse. Therefore, natural resource abundance only appears to constitute a curse in countries where the quality of the institutions is low.

It is also possible that resource abundance has a direct impact on the quality of institutions that are established in resource-rich countries. A low level of property rights protection allows the ruling elite to appropriate a greater portion of the country's natural resource rents. Therefore, the ruling elite in a resource-rich country may have the incentive to retain weak institutions or even weaken them further. This, in turn, makes it less likely that resource-rich countries will develop sufficiently strong institutions to escape the resource curse.

Trade

International trade has long been linked to economic growth and development. More recently, however, research has turned its attention to the effect of international trade on political variables such as corruption and rule of law. There are two avenues through which trade can influence political variables. The first is indirect, via higher national incomes. Empirical evidence has shown that countries that are more open to trade tend to have relatively higher national incomes. National income is in turn positively associated with stronger political institutions, as richer countries can afford to invest more in improving their institutional framework. The second avenue through which trade can affect institutions is direct. Proponents of this view argue that international trade acts as a disciplinary measure; countries that engage in trade are induced to improve their institutions in order to be competitive on the international stage.

Geography is believed to play an important role in determining the extent to which a country is open to international trade. A country's level of "natural openness" depends to a great degree on its geographical characteristics, such as length of coastline, remoteness, and island status. Furthermore, transportation costs are significantly affected by geography. Access to the sea or navigable rivers has historically been very important for trade, while natural barriers act to hinder

trade. Europe, composed to a great extent of peninsulas and large islands and with several large, navigable rivers, is characterized by a high degree of natural openness to trade. In contrast, Africa has little coastline relative to its geographical area, many landlocked countries, and few navigable rivers, with the Sahara acting as a large natural barrier. As a result, Africa is characterized by a low degree of natural openness to trade. These geographical differences can account for some of the observed differences in trade openness exhibited by the two continents and may as such contribute to the differences in the quality of their political institutions.

Even within Europe, there is reason to believe that geography has had an important effect on trade, which has carried over to political institutions. Daron Acemoglu, Simon Johnson, and James Robinson argue that Atlantic trade was largely responsible for the rise of Western Europe between the years 1500 and 1850. Atlantic trade not only brought about economic growth but also acted as an impetus to significant institutional change. Therefore, European countries with access to the North Atlantic gained an advantage in both economic and institutional terms.

POLITICAL ECONOMY OF RESOURCES

Political economy refers to interdisciplinary studies drawing on economics, law, history, and political science to explain how political institutions, the political environment, and economic systems affect the factors of production, namely, labor, land, and resources. Originally, political economy focused on the conditions under which production and consumption were organized within and among nation states. Thomas Malthus, Adam Smith, David Ricardo, and Karl Marx were proponents of this tradition. Today in geography, political economy refers to neo- and post-Marxian interpretations of labor, land, and natural resource

exploitation and development and underdevelopment in the global economy. This entry will focus on the latter factor, the political economy of resources.

Dependency Theory and the World Systems Approach

Dependency and world systems theories explain economic development in various parts of the world at different times in history. In the 1960s, dependency theory and the world systems approach used the terms *core* and *periphery* to describe and analyze global political and economic systems. According to both theories, core countries have high levels of industrial production capacity, use advanced technologies, and dominate international trade, while the periphery describes agrarian societies and those with modest industrial infrastructures, which largely serve core country resource and market needs. The core holds political and economic power over the periphery, which is reflected in control over trade and finance. This pattern was particularly prevalent under colonial rule, when, for example, transportation systems were developed mainly to provide the core countries access to the resources and markets of the periphery. This situation formally ended with decolonization following World War II, but the legacy of colonialism lives on in many parts of the world, and dependency in terms of trade and finance assures the core of continued economic and political dominance. The semiperiphery, with its newly emerging economies, has a higher level of autonomy and has experienced significant economic development over the past few decades based on the comparative advantage of low-cost labor and, in some cases, abundant resources.

The world systems approach examines core-periphery relations as the functional evolution of the world capitalist economy. The needs and problems of the underlying system of economic and political relations is its focus. Dependency theory adopts the standpoint of the periphery to examine the functioning of core-periphery interactions. Its adherents developed an extensive explanation of comprador elites in the periphery who facilitate colonial or neocolonial interests.

Economic Globalization and Resources

During the past quarter-century—guided by neoliberal economic and political theory—global investment production and foreign trade increased rapidly. The World Trade Organization, the International Monetary Fund, and the World Bank have promoted neoliberal policies to spur economic globalization. However, the major players behind the increase in worldwide resource exploitation and economic production are multinational corporations.

The rise and dominance of multinational corporations are closely related to advanced technological development (in communication and transportation in particular) and advanced global corporate management aided by free trade regimes. As a consequence, economies of scale and marketing and the exploitation of resources have expanded geographically. Traditionally (under colonial regimes), core-country industrial corporations would invest in resource extraction in countries of the periphery and process resources as raw materials in factories in the core country. Today, global markets create a new geographical division of labor whereby core corporations not only invest in raw materials extraction (through mining or from plantations) but also relocate labor- and resource-intensive manufacturing to peripheral countries where low-cost labor and sometimes less restrictive environmental regulations prevail. In pursuit of growth and profit, multinational corporations contract with local mining companies, plantation owners, or agribusinesses to secure raw materials and establish finance and trade networks to move not only materials but also their economic value to the global market.

Today, multinational corporations invest in countries that still have large deposits of coal or other cheap energy sources to be used in process manufacturing of aluminum, iron, steel, cement, and concrete and in paper and pulp production. China, India, Brazil, and Russia (in the semiperiphery) are among the countries of interest, and their economies have been growing rapidly. Also, corporate capital uses cheap labor in countries with few regulatory controls to operate a global assembly line for the production of electronic information technologies. This pattern of

development has led critics to question the desirability of economic globalization.

Resources and Sustainable Development

Economic development of the periphery and semiperiphery forces the poor in these countries to bear the brunt of unsustainable growth. Severe damage to ecosystems that support local livelihoods has been widely noted. In response, local communities increasingly protest against the entry of large mining and oil companies and other foreign businesses. Conflicts in the Niger Delta and the Amazon rain forest are examples of the effects of global-scale exploitation of resources. Livelihood-linked environmental consequences include depleted soils, deforested lands, polluted groundwater, ecosystem destruction, climate change, and extinction of species and ways of life.

In response, core countries and multinational corporations have sought a remedy in the idea of sustainable development, defined by the World Commission on Environment and Development as development that meets the needs of the present generation without compromising the ability of future generations to meet theirs. The proposal suggests that economic growth can be sustained while averting or reducing many environmental and livelihood threats. International programs and treaties ranging from the Millennium Development Goals to the United Nations Framework Convention on Climate Change attest to the popularity of the idea.

The experience with the practice of sustainable development has left many to doubt its efficacy. The problem of climate change illustrates some of the dilemmas related to the promise of sustainable development. Among these is the fact that the continued economic growth of the core countries has so far exacerbated the buildup of greenhouse gases. Despite the rapid introduction of so-called clean and green technologies, in the new century, the largest source of greenhouse gas emissions by far are the core countries of North America and Europe and Japan, Australia, and New Zealand. On a per capita basis, this bloc averages emissions in excess of 15 tons/yr. (year), while the peripheral countries of Asia, Africa, and Latin America average less than 3 tons/yr. The requirement to avert further warming is reduction of the world per capita

average to 3.3 tons. Recent research has shown that this target can only be met if the United States and other core countries dramatically lower their emissions over the next 10 to 20 yrs.—a task that requires a shift to “steady-state” rather than growth-based economies. Additionally, the only mechanism to date to regulate greenhouse gas emissions focuses on countries but, significantly, not multinational corporations. Yet many of the decisions that affect the volume of greenhouse gas emissions have been made by corporate capital acting beyond the reach of governments. Failure to address the so-called corporate greenhouse compromises the world’s ability to address the most comprehensive threat to livelihoods and the health of the planet.

The field of political economy of natural resources has now embarked on a search for a genuinely equitable and sustainable future. There is increasing interest in “bottom-up” strategies proposed by civil society to construct a postglobalist political economy in which the geography of economy, politics, and the environment is centered on empowered communities rather than on global capital and technologies.

POLITICAL GEOGRAPHY

Political geography is concerned with the interplay of politics and geography. Precisely how the geographical informs the political, as well as how the political informs geography, is open to discussion, interpretation, and debate. For instance, at the turn of the 20th century, political geography was preoccupied with explaining how the physical and environmental characteristics of the Earth shaped and dictated the world of the great powers of Europe, but over time, such explanations would be rejected. At the beginning of the 21st century, political geography is far more diverse in its subject matter, more cosmopolitan in extent, and open to examining a range of questions concerning, for example, territory, sovereignty, identity, and power at the supra- and subnational scales of analysis. Despite these shifts, contemporary political geography remains engaged with fundamental questions about the complementary linkages between geography and politics.

History of Political Geography

Origins

As one of the three traditional pillars of human geography, social or cultural and economic geography being the other two, political geography can trace its historical roots to the German geographer, Friedrich Ratzel. In 1887, Ratzel published *Politische Geographie*, in which he introduced the idea that the size of a state is a

measure of its cultural prowess. Moreover, for societies to survive and prosper, territorial expansion at the expense of weaker states was considered to be a natural and necessary process. Ratzel used the term *Lebensraum*, or living space, to describe such areas of expansion. Making such direct and causal linkages between environment, society, and culture was not uncommon in the field of geography, which at the time was primarily found in European universities, and such approaches were in fact considered to be scientific in nature.

Paralleling Ratzel's writings and ideas concerning the organic nature of states were those of the English geographer Sir Halford Mackinder. In his 1904 work, *The Geographical Pivot of History*, Mackinder established the underpinnings for his heartland theory, which states, "Who rules East Europe commands the Heartland/Who rules the Heartland commands the World-Island [i.e., Eurasia]/Who rules the World-Island commands the World" (p. 186). Mackinder's heartland theory was used to illustrate the geostrategic threats that the British Empire faced, namely, from Germany and Russia. Subsequently, in the aftermath of World War I, Mackinder would apply his ideas as he and other geographers were consulted about the redrawing of national borders in Europe at Versailles.

Geopolitics and Its Critics

Though Ratzel and Mackinder are often considered to be the founding fathers of political geography, it was their use and application of geography to serve the national interest that led to the development of what the Swedish geographer Rudolf Kjellén called "geopolitics." Primarily concerned with territorial disputes and claims between Norway and Sweden, Kjellén was the first to use the term to describe the practice of creating geographical justifications in the pursuit of national goals. Considered to be an integral component of political geography today, geopolitics emerged in the early 20th century as a tool to justify and shape foreign policy.

During the interwar period of the 20th century, several Germans were drawn to the ideas developed by Ratzel and Mackinder, and they developed a particular type of geopolitics that aimed to

serve the German state. The most prominent German geopolitician was Karl Haushofer, who is credited with developing and promoting the idea of the "pan-region." According to the German school of geopolitics established by Haushofer, the world could be divided into four autarkic, or self-sufficient, pan-regions (i.e., Pan-America, Eur-Africa, Pan-Russia, and the East Asian Co-Prosperity Sphere), with Germany acting as the ruling state of the Eur-African pan-region. Though Haushofer had connections with the Nazi leadership, the influence of his geopolitical ideas and visions on Nazi expansionism remains debatable.

Concurrently, the American geographer Isaiah Bowman engaged in a political geography that was more concerned with taking stock of the world's political problems than promoting the national interest, though he was not entirely neutral, since he was chief geography advisor to the U.S. government in the years following World War I. Bowman authored *The New World: Problems in Political Geography* in 1921. His work covered an enormous range of topics—many of which are just as salient at the beginning of the 21st century as they were at the beginning of the 20th—such as border issues and disputes around the world, the political geography of natural resources, and the status of ethnic minorities. Despite Bowman's efforts to distinguish political geography as scientific and objective, versus a geopolitics driven by state interests and ambitions, the enterprise of political geography would be tainted by its association with geopolitics, in particular, the geopolitics of the Third Reich.

Political geography and geopolitics remained very uneasy bedfellows throughout the Cold War. Due, in part, to the damning associations that geopolitics had with Nazi aggression and atrocities, political geography quickly faded into the background in both policy and academic circles. With little innovative or substantive research emerging to support or to advance thinking in the subfield during this period, political geography was relegated to the classroom. Perhaps the most notable exception to the retreat of political geography during this period came from the works of the French-trained geographer Jean Gottman. The central premise underlying Gottman's work was that state formation, and the system of states at large, was a function of centripetal and centrifugal

social forces. The integration of the state system was therefore determined by the degree to which these competing forces balanced each other out. Gottman can be considered ahead of his time, because his work did little to resuscitate or revive the subfield, though it would later be considered pathbreaking by many. This is not to say that political geography, and in particular geopolitics, disappeared entirely during the Cold War; rather, it was being practiced by policymakers, academics, and others, who were careful not to invoke the term *geopolitics*. In its place, an entirely new set of stylized terms and ideological concepts emerged, for instance, “the Truman doctrine,” the “strategy of containment,” and “domino theory.” Though such ideas were clearly grounded in geographically informed foreign policies and strategies, at the time, they were not considered to be geopolitical or geopolitics per se.

The Quantitative Revolution

It was not until the 1960s that political geography began to emerge from its marginalized position, especially when compared with its counterparts, social and economic geography. Drawing from developments and advances across geography and other social sciences, but most notably political science, political geographers began to move beyond providing descriptions of the geographic distribution of states and inventories of their attributes. In large part motivated by what is referred to as the quantitative revolution in social science, geographers began to apply statistical techniques and quantitative methods to their own research. Moreover, it was during this period that theories to explain spatial patterns and behavior were constructed and used to guide research. The blending of quantitative methods and location theory spawned what is referred to as spatial analysis, which in turn attracted many new geographers to the discipline.

One topic within political geography that was identified to be especially well suited for such spatial analyses was elections. Though electoral geography can trace its roots back to the ecological analyses of the French geographer Andre Siegfried and his work in the Ardeche region of France, it was not until the 1960s that political geographers began to systematically analyze and

attempt to explain democratic outcomes from a geographic perspective. Several political geographers began to concern themselves with explaining voting patterns, assessing the geographical influences on voting (e.g., neighborhood effects), and evaluating how votes are translated into seats across a democracy. Though elections can indeed be characterized as the ideal political geographic event to examine with spatial analysis, the politically charged atmosphere of the 1960s would also have profound and lasting impacts on the social sciences, political geography included.

Political Economy

The sociopolitical movements, unrest, and upheavals that swept across the United States and Europe in the late 1960s ushered in notable intellectual changes in both British and American universities during the 1970s. Perhaps the most influential change in political geography came with the adoption of political-economy approaches across the social sciences, based on Marxist thought, to understand and explain the historical bases, conflicts, and consequences of capitalism. Such approaches allowed political geographers to reorient, reexamine, and reevaluate questions in political geography in intellectually innovative and engaging ways. From core-periphery relationships to the inequalities and inequities that the capitalist world economy produced, the topics that Marxist political economy addressed spawned and invigorated an entire generation of so-called radical geographers. Moreover, such radical approaches provided an attractive alternative for many who found the spatial analytic approach too staid and limited in theoretical power. Despite differences and divisions concerning how political geography was to be engaged in, the beginning of the 1980s marked a resurgence of interest in the subfield.

Postmodernism and Poststructuralism

Just as political economy approaches to understanding the world economy transformed the social sciences in the 1970s, the diffusion of so-called postmodern and poststructuralist perspectives in the late 1980s and early 1990s attempted to reorient and challenge modes of

inquiry, thinking, and knowing across the social sciences. In particular, notions of objectivity and the singular nature of theory in social science were questioned, as was the neutrality of language and discourse. Though criticized for their failure to extend or contribute to knowledge in itself, such approaches were embraced by several political geographers. One of the most noteworthy developments within political geography during this period was the development of “critical geopolitics.” Concerned with how and why geopolitical discourses are constructed by elites, and practiced and understood vis-à-vis foreign policy, the emergence of critical geopolitics marked the reclamation of the term *geopolitics* by political geographers and also permitted political geographers to shed much of the baggage once associated with German geopolitics.

The Role of the Nation-State

Notwithstanding discussions about how social science, including political geography, should be practiced, the dramatic transformation of the world political map during the late 1980s and 1990s provided much fodder to renew interest in and expand research and extend thinking on matters of great relevance to the subfield. The end of the Cold War, marked by the fall of the Berlin Wall, the collapse of communism across Eastern Europe, and the subsequent disintegration of the Soviet Union, not only altered the balance of world power but also forced many—and especially political geographers—to reflect on and reexamine their worldviews. Similarly, the emergence of new political arrangements and economic realities across the globe, for instance, the creation of a multinational coalition to wage war in the Persian Gulf and the consolidation of the European Union, raised questions about the role and future of the nation-state. With the diverging processes of, on the one hand, geo-economic integration (e.g., the European Union) and, on the other, geopolitical disintegration (e.g., the break-up of the Soviet Union, war in the Balkans), political geographic research tackled more and more questions beyond the traditional “global,” “nation-state,” and “local/urban” scales of analysis and focused more on the politics of nonstate actors and groups.

Political Geography in the 21st Century

This trend of examining and analyzing issues beyond and below the scale of the nation-state continues within political geography at the beginning of the 21st century. Events such as the terrorist attacks against the United States in September 2001, the subsequent “war on terror,” the rise of religious fundamentalism, ongoing ethnic conflicts, and the increase in the number of democratic elections held around the world have indeed served to reinforce the significance of political geography. Furthermore, the social reactions to, and political consequences of, these events have also generated new and notable areas of interest for political geographers. For instance, the events surrounding the terrorist attacks of September 2001 and the wars waged in Iraq and Afghanistan continue to raise several questions about the nature of democracy, territory, sovereignty, and identity as well as unforeseen issues regarding citizenship, privacy, and individual human rights.

Complementing these “political” questions are those related to “geography,” which arguably represents a relatively new thematic area for political geographers in the 21st century. In part due to the development and rapid diffusion of geographic information technology, namely, geographic information systems (GIS), the global positioning system (GPS), and remote sensing (RS), environmental issues and awareness have indeed reentered political geography, and public discussion more generally. Though there may be a relatively high level of consensus regarding whether or not climate change and global warming are indeed occurring, the politics of climate change and global warming—or what can be done about them, who will do it, and where it will be done—remains far more uncertain, if not contested. Similarly, conflicts over scarce natural resources, such as water, land, and oil, are becoming more common, not only between states but also at the supra- and substate levels. Finally, the application of geographic information technology itself, to watch over individuals and groups, to monitor the environment, to measure natural resources, to control public and private spaces, and to wage and sustain war, also raises a host of new and unexpected political geographic questions, consequences, and concerns.

It can be surmised that contemporary political geography is both a broad and a deep field of inquiry, like its progenitor, geography. Whether or not the diversity of subject matter and approach in political geography is its greatest strength, or most noteworthy shortcoming, remains open to discussion. Nevertheless, perhaps one of the most significant developments within political geography over the past century is the recognition that knowledge, understanding, and geography itself are historically contingent. In other words, to understand the concepts, objects, and subjects of political geography, an awareness of the sociohistorical context from which they emerged and in which they exist is central. A parallel development that is just as significant is the expansion of the subfield beyond the Anglophonic realm. In this regard, political geography is currently far more cosmopolitan, diverse, and inclusive in terms of those who practice it, what it is concerned with, and how it is engaged in than at any other time in history.

The circumstances, events, and approaches discussed above have also led to the rediscovery of political geography, and geography at large. Some come to political geography fairly knowledgeable about its history and methods, while others are far less aware of its evolution and implications. Though recent discussions about the environment and geography as they relate to politics are unlikely to invoke the particular ideas of Ratzel or his contemporaries, it is not uncommon to come across ideas in the mass media or popular science that suggest environmental determinism. In this respect, has political geography come full circle in a little more than a century, with relatively little to offer, and are we doomed to repeat history? On the contrary, and as alluded to above, at no other time in history have political geographers been more keenly aware of and more actively engaged with understanding how geography shapes and informs politics and, conversely, how politics shapes and informs geography. It is precisely this understanding that makes contemporary political geography a vital and key component of geography. From long-standing questions about the geopolitics of inter- and intrastate conflict to critical approaches to how scales of analysis are themselves politicized, political geography will continue to be a vibrant and engaging enterprise.

POLYCHLORINATED BIPHENYLS (PCBs)

Polychlorinated biphenyls (PCBs) are a class of odorless, liquid, synthetic organic chemicals containing chlorine, hydrogen, and carbon that persist in the environment following use. PCBs have many applications, including dielectric fluid in electrical capacitors and transformers, hydraulic

fluids and lubricants, flame retardants, plasticizers, and carbonless copy paper. PCBs have been manufactured and used worldwide since their introduction in 1927, with Monsanto controlling the U.S. market since 1935 and accounting for half the global production.

PCBs have been widely used for more than 75 years, with about 1.65 million tons of cumulative production worldwide. These chemicals have several advantages: fire resistance, low electrical conductivity, high resistance to thermal breakdown, and high chemical stability. Unfortunately, due to their persistence, bioaccumulation, and biomagnification, they can cause several adverse health effects as they collect in fatty tissues in humans and other exposed animals in both terrestrial and aquatic systems. These include liver and immune system disorders, irritation of the skin and eyes, reproductive and developmental effects, and probably several types of cancer.

The United States banned the manufacturing, processing, distribution, and use of PCBs with the passage of the Toxic Substance Control Act in 1976. Internationally, PCBs are one of nine chemicals slated for elimination by the 2001 Stockholm Convention on Persistent Organic Pollutants, which took effect in May 2004 and will be fully implemented by 2025. Despite these efforts, large volumes of PCBs still exist in the environment. Disposal options include incineration, ultrasound, irradiation, chemical and thermal treatment, and special landfills for PCB-contaminated sediments and articles.

PCBs have been implicated in several major incidents of environmental contamination. Probably the first major case was in 1968 in Kyushu, Japan, where nearly 1,800 residents fell ill after eating Kanemi rice bran oil (yusho) contaminated with PCBs. Subsequently, more than 50 people died. A similar incident occurred in Taiwan in 1979. In several areas of the United States, thousands of chickens and hogs had to be slaughtered because they ate PCB-tainted feed. General Electric (GE), a large user of PCBs, dumped 1.3 million pounds of the chemicals into the Hudson River, New York, from 1947 until 1977. An early case of environmental justice involved the creation, in 1982, of a landfill for PCB-contaminated soil in rural Warren County, North Carolina, a predominantly poor African American community.

Following years of PCB dumping by paper mills into the Fox River and Green Bay, Wisconsin, a natural resource damage assessment was conducted, leading to a settlement in 2004 of \$60 million in compensation and restoration costs. Additional PCB dumping, causing concern over fish and shellfish contamination, has been widespread in the Great Lakes region. High levels of PCBs have even shown up in native peoples and wildlife in Northern Canada and Alaska due to long-distance transport. Most recently, nine pig farms in Ireland had used PCB-contaminated feed, resulting in the withdrawal and disposal of pork-containing products purchased in Ireland between September and December 2008.

POPULAR CULTURE, GEOGRAPHY AND

The term *popular culture* is often used colloquially and by commentators in ways that are complex and contradictory. Common to all definitions, though, is the idea that popular culture is associated with mass consumption. Popular culture can thus be seen to include everything from magazines, movies, and television to Internet phenomena such as Facebook and MySpace. Popular culture generally refers to the field of material culture and practice that is associated with everyday people, usually in opposition to “high” culture, which refers to the material culture and practice associated with socioeconomic elites. Alternatively, popular culture can refer to a globalizing

Western culture that is seen in opposition to local folk cultures. In either case, popular culture is usually framed in negative terms, although this has changed in the social sciences and humanities over the past few decades.

Geography has engaged with popular culture in two ways. In the first, popular culture is theorized as a commodity, with a few sites emerging as sites of production, complemented by broader patterns of consumption. In the second formulation, popular culture is theorized as a purveyor of ideology, with geographers considering the messages and ideologies contained within it—either as a source of anxiety and danger or as a tool for creating communities. This entry first examines the origins of popular culture and then discusses the popular geographies of production and consumption. It then explores the ways popular culture is theorized in opposition to folk culture as part of the larger analysis of globalization and concludes with a look at poststructuralist approaches to popular culture and its meaning.

Origins of Popular Culture

In its original usage, *popular culture* was pejorative, referring to the culture of the masses, which was seen as normatively inferior to that of socioeconomic elites (high culture). This social denigration and devaluation by and large continue to the present day in popular discourse and to a certain extent in academic discourse as well. However, as cultural authority has been increasingly undermined in Europe and North America since the 1960s, the line between popular and high cultures has become increasingly difficult to define. Indeed, the rise of technologies associated with Web 2.0 (including user-generated fare) has ostensibly led to a process of aesthetic democratization, with fans now exerting more and more control over creative processes, and even populist cultural commentators such as *Rolling Stone* magazine and MTV are losing their authority. This relationship between high and popular culture, however, is not static. High culture draws inspiration from popular culture and vice versa, thus blurring the distinctions between them. This is most apparent when these two forms of culture share a medium. When opera legend Luciano Pavarotti performed alongside the rock band U2

(in “Miss Sarajevo,” 1995), was the performance popular or high culture? While aesthetic quality is purportedly the criterion on which such a distinction is based, in reality, it has more to do with market segmentation. The more popular a cultural artifact becomes, the more “debased” it is perceived to be. Thus, the aesthetic assessment of culture should be understood to be just as much about identity and subjectivity as it is about the cultural artifact itself.

Popular Geographies of Production and Consumption

The use of the term *popular culture* masks a great variety of strands within consumerist culture. For example, within popular culture, there exists a strand of artisanal popular culture, which consists of the more popular versions of high culture, complete with a focus on the auteur and the individual producer. As an example, one could easily turn to Stephen King’s novels or the graffiti of London’s Banksy. Another strand of difference to be found within popular culture is that of the mass media—such as television, magazines, music, radio, and some of the more traditional aspects of the Internet. These are generally the most corporate of popular culture artifacts, requiring large institutions to prepare and distribute material on a regular basis. A final strand worth noting is participatory popular culture, which includes fashion, sports, and the aforementioned Web 2.0 phenomena. What unites this strand is the more active role of the consumer (or participant); rather than just consuming a prepackaged product, the participant shapes the activity itself.

These three strands of popular culture reflect various scales of production, with the mass media generally at the macroscale, artisanal popular culture at the mesoscale, and participatory culture produced in and through consumers’ bodies. However, these scales are simply categories and do not reflect the interconnections between scales in the production of popular culture; for instance, while fashion is intimately connected to bodies and individual stylistic choices, it is also connected to corporate design and distribution networks. Networks such as these, although relatively stable, are always shifting in an effort to maintain the popularity on which their products are based. Thus, while certain cities have

Captain America, foreground, and Spiderman greeted many Pentagon-assigned service members and their children on April 28 for the unveiling of a custom comic book for members of the armed services. One of the oldest and most recognizable superhero characters in American comic books, Captain America sprang from the wartime political culture during World War II.

Source: Tech. Sgt. Cherie A. Thurlby, United States Air Force (<http://www.defenselink.mil/news/newsarticle.aspx?id=31325>).

emerged as command-and-control centers for the popular culture industries, such as Los Angeles, New York City, London, Paris, Milan, Cairo, Mumbai, and so on, this centrality is contingent on the ability of these centers to market difference from other “exotic” destinations. For instance, denim jeans have become de rigueur around the world despite their origins in the American West. Similarly, reggae music from the Caribbean has become commodified and sold around the world by record companies based in the United States and elsewhere.

The distribution of popular culture around the world has been eased by several rounds of time-space compression. The earliest of these relevant to popular culture was the invention of the printing press, which boosted the distribution of copies of the Bible in vernacular languages and in turn boosted literacy rates. Thus was the market for pamphlets and other literature constructed. While this initial foray into mass media took quite some time to get under way, its impacts are still manifest today. In a world with rapidly innovating media,

such as radio, television, and the Internet, that are used to distribute popular culture (and news about popular culture), public and private spaces alike are colonized and commercialized. This has led to concerns over the content and impact of popular culture even as it becomes nearly impossible to geographically remove oneself from its grasp.

Globalization of Popular Culture

Linked to these concerns is a long-standing tradition within the subdiscipline of cultural geography. For many decades, cultural geographers have analyzed the impact of time-space compression on cultural forms around the world. This time-space compression is often referred to as globalization. *Globalization* is itself a much debated term, but in this context, it is couched as shifts in labor and other markets resulting from the transportation and communication revolutions and consequent changes in the global division of labor. Certainly in the West, and to a lesser extent in other parts of the world, goods from various parts of the world are on sale and at low prices heretofore impossible. This not only has economic implications but also has implications for perceptions of heterogeneity/homogeneity and cultural distinctiveness.

Popular culture itself has come to reflect these changes, not only outsourcing production of cultural artifacts to sites of lower wages and regulation but also seeking commodifiable difference to market and sell, as described above. Some believe that this growth of a “global culture” is a normative good, leads to declines in ethnic and religious intolerance, and heads off conflict through increased interaction with cultural “others.” Obvious examples include the growth of the practice of yoga in the West as a form of exercise and meditation and the growth of “ethnic” restaurants in small towns. Others view this as the co-optation of folk cultures, which are local, relatively stable cultures that are distinct from outside cultures. These cultures find themselves essentialized and frozen in a premodern position of “exotic-ness.” An obvious example of this is the new genre of “world music,” which depends on its “exotic” inputs to differentiate it from domestic music production. Both of these perspectives, the positive and the more pessimistic, are linked in that they view the cosmopolitan West as universal, or

incorporative of all cultures, while other regions are defined by their particularity and uniqueness.

Thus, either perspective can be understood as engaging in Orientalism, in which the West is considered progressive and tolerant, while the remaining regions of the world are relegated to their particular “ethnic” pasts. Globalization in this perspective can be seen as contributing to the discursive elevation of the West above other parts of the world through this claim to universalism. A criticism of that claim is that the inclusion of others’ cultures comes only on the terms of the West and its consumers. This criticism is most often leveled at the United States, which, as the global economic hegemon, has been asserting its desire for free trade and increased globalization over the past several decades. When this criticism is leveled at one country in particular (such as the United States), or at an elite few, that country is charged with cultural imperialism, because it is seen as constructing an artificial centrality in another country’s social life; whereas imperialism makes a country dependent on trade with its colonizer, cultural imperialism makes a country dependent on its relationship with the hegemon for self-understanding. Thus, the distribution of popular culture is about much more than markets—it is about identity, subjectivity, and intellectual decolonization.

In the popular/folk culture dichotomy, the difference is expressed through temporality, with popular culture being modern and folk culture being premodern or traditional. Modern social scientists have long anticipated (while the subalterns have feared) the final eradication of folk culture at the hands of a rapidly globalizing (Western) popular culture. However, this horizon of cultural homogeneity seems as far away as ever. Explanations tend to incorporate as an assumption that market domination creates cultural homogeneity, but this has simply not turned out to be true. This assumption overly conflates consumption with culture. Indeed, culture far exceeds consumption, including religion, language, diet, ritual, and so on. Thus, even if two people watch the same Will Ferrell movie, their reasons for watching the movie may be quite different. For instance, watching Will Ferrell could be a way to demonstrate youth, economic class, or something else entirely. In other words, the cultural meanings that the movie is laden with still vary according to

geography; thus, globalization of popular culture artifacts is not necessarily the same as Americanization. The domination of popular discourse by the frame of globalization for the past 20 years has led to the equation of popular culture with the commodities that are consumed. However, as this last example hints, popular culture is not just artifacts but what is done with them—identities are performed and meanings are inscribed.

Meaning and Ideology in Popular Culture

Much as the original printing press led to political shifts within the world of Christianity (i.e., the Reformation), new media technologies have often led to anxiety on the part of authorities, who feared that their alienation from flows of information would undermine their power. For example, the rise of new technological platforms at the nexus of information and entertainment (such as instant messaging, video-to-phone downloads, etc.) has generated a rash of concern by parents about the messages that their children are receiving, in part because the technological competence of parents is often less than that of their children. Similarly, governments have often used propaganda on their own or other populations but feared their own population's susceptibility to the same. This governmental desire to control the mediation of geopolitical content led to some of the first academic studies of audiences and the media. Inherent in this framing of "the problem" was an understanding of audiences as fundamentally accepting of propaganda, based on the then recent success of Nazi and Fascist propaganda in Europe. Fear of a similar communist ascendancy animated the Frankfurt School, a collection of scholars including Theodor Adorno and Max Horkheimer. Their analysis of the "culture industry," the aggregation of entertainment-focused corporations that claim to respond to consumer desires but instead produce (and standardize) those self-same desires, adopted the same perspective of passive audiences as the earlier studies of propaganda did but used it to advance an argument about capitalism and the way in which it is perpetuated. They argued that the effect of the culture industry was increased consumer passivity in the face of injustice, drawing parallels to the "bread and circuses" of ancient Rome.

Antonio Gramsci, who was writing at roughly the same time as Adorno and Horkheimer (but whose work became available in English much later through translation), was a communist jailed during the Fascist era in Italy. He turned his attention to the apparent ability of the capitalist state to forestall the communist revolution that Marx had argued was inevitable. He argued that the capitalist state produced a hierarchy in which bourgeois culture was superior to that of the masses. Thus, workers were alienated from their own culture as they sought to associate themselves culturally with more privileged groups. Gramsci's theory of hegemony was thus very similar to that of Adorno and Horkheimer in that it theorized popular culture to be a placebo that duped people into fundamentally irrational behavior (in that they ignored their own interests). The key difference between these two theories, however, is that hegemony implies some degree of compromise—elites have to make their culture interesting and recognizable to the lower classes. In both cases, however, the denigration of popular culture can be understood as a weapon used to alienate workers from their own popular culture. Gramsci argued that the communist revolution would remain on hold until an independent popular culture could foster an "authentic" class consciousness.

The next major rethinking of ideology and popular culture began in the 1960s with a school of thought that has come to be known as Cultural Studies. It takes as a starting point that popular culture is important and relevant but generally eschews the pessimism that is associated with earlier views of popular culture. Most of the work associated with Cultural Studies now has moved away from structural accounts, although Marxism remains a strong influence. However, post-structural theorists have taken center stage and have begun to change the working assumptions of popular culture, namely, that the audience is a passive recipient of others' ideologies. For example, Michel de Certeau has argued that institutions (e.g., Adorno and Horkheimer's culture industry and Gramsci's capitalist state) enact strategies to achieve their goals, while individuals, who are by definition more nimble than institutions, enact tactics to achieve their own goals. In the context of popular culture, this means that consumers of popular culture can take it and

rework it into something useful to them, taking the parts that they like, leaving others, or perhaps re-imagining the whole thing. An often cited example is the rise of “slash” fan fiction, in which (presumably) heterosexual characters from popular culture (e.g., Kirk and Spock from *Star Trek*, Xena and Gabrielle from *Xena: Warrior Princess*) are rewritten by fans as being in homosexual relationships with each other. Often this is done against the express wishes of the copyright holders, and it illustrates the problem with the propagandistic model of audiences—it simply does not explain the complexity of audience responses.

Audience responses, however, are not random and instead are rooted in interpretive communities that are often geographic in origin. David Livingstone’s work on the re-interpretation of theory as it travels has argued that there are two particular geographies to the interpretation of texts (and this can be broadly extended to include all forms of popular culture). The first, cartographies of textual reception, generally refers to differences in the interpretation of texts between regionally based cultural/linguistic communities. The second, cultural geographies of reading, refers to the structuring elements found in the processes of meaning making among networked identities (university students, evangelical Christians, etc.). Reading is thus not an isolated act but rather one that occurs in a social context. Therefore, the meanings that are available to any given reader are limited by the social context in which that reading is undertaken. This tension between the conceptualizations of popular culture as a structuring force on identities, and simultaneously as a cultural resource to be used tactically by consumers as a way of performing their own identities, is a realm of ongoing work by geographers.

POPULATION AND LAND DEGRADATION

The debate about population and land degradation has spanned decades, if not longer, with contrasting perceptions of whether people are victims of land degradation or land is a victim of anthropogenic influences. While the debate rages on, the impacts of land degradation on human well-being and development are self-evident. *Land degradation* is commonly defined by the United Nations Convention to Combat Desertification (UNCCD) as the reduction or loss of biological and economical productivity and of the complexity of terrestrial ecosystems. This includes soils, vegetation, other biota, and the ecological, biogeochemical, and hydrological processes that operate within ecosystems. This definition does not characterize degradation as entirely anthropogenic, despite unsustainable land use by humans being a key driver of land degradation.

Population Growth

Human population growth has been cited as a leading factor in land degradation and environmental change in general. Global population increased from 5 billion in 1987 to 7 billion in 2009, an average annual growth rate of 1.4%, with Africa and West Asia recording particularly high growth rates (Figure 1). This increase in population, together with the increase in the gap between the rich and the poor, in the relative access to goods, and in income-earning opportunities, has led to increased demand for food and energy, putting pressure on available environmental resources such as freshwater, fisheries, agricultural land, and forests.

Population changes are further influenced by forced and economic migration, which in turn affects settlement patterns, resulting in migrant refugees who are internally displaced. An estimated 25 million people have been forced to migrate as a result of environmental factors, with approximately 200 million threatened by displacement not only from environmental factors but for political and ethnic reasons as well. An estimated 2 billion people depend on dry lands that bear a legacy of land degradation, and 90% of them live in developing countries.

Migration

Rural to urban migration, or urbanization, is an especially prevalent trend in developing countries. An urban increase of 44%, from 28% to 29%, has been noted in northeast and southeast Asia and is predicted to reach 59% by 2025. An estimated 1 billion people reside in informal urban settlements around the world, with no proper housing or basic services, which has contributed significantly to urban and suburban spread and uncontrolled land transformation. High concentrations of the urban population reside along coastal areas, exerting undue pressure on coastal and marine ecosystems. While these direct causes of land degradation are important, it is the formal urban settlements that have been shown to exert greater pressure indirectly on land.

The multifaceted relationship between migration, urbanization, and, in turn, environmental change leads to natural disasters and land and ecosystem degradation, while consequently changing land use and the demand for ecosystem services. For example, the persistent shift from cereal to animal products and the recent move toward biofuels add to the demand for increased farm production, with unfavorable consequences for farmland rather than forestland. Negative impacts of urbanization, such as pollution, have been detrimental to human health. In Africa, it has been argued that children living in sub-Saharan cities in slums are more likely to die from waterborne diseases than are rural children. Ultimately, the population burden on natural resources and sustainability may increase as populations increase.

While population increase is a key driver of land use change and degradation, it is not the only factor involved. Economic development, poverty, and globalization are but some of the exacerbating factors driving unparalleled land use change and degradation. Globalization alone has economic, environmental, technological, political, and cultural dimensions, creating not only new opportunities but threats as well.

The Population and Land Degradation Debate

Population growth has resulted in increased demand for agricultural productivity, higher

Figure 1 Population growth by region

Source: United Nations Environment Programme. (2007). *Global Environment Outlook: Environment for development* (GEO-4; Figure 1.4, p. 21).

incomes, and changes in consumption patterns. Inequitable land distribution, a legacy of colonialism and societal/cultural conflicts, has exacerbated the problem. While the causes of this multifaceted phenomenon have been contentious, the growth of the human population and the increase in anthropogenic influences receive the most blame for the current state of land degradation, especially in developing countries, where a significant portion of the population is dependent on subsistence farming.

Poverty also is a major cause of land degradation, with population growth and poverty mutually reinforcing each other to bring about a spiral of degradation. The neo-Malthusian hypothesis warns about the risks and impacts of population growth outstripping the natural resource demand for food and shelter. The neo-Malthusian theory further regards population growth and the environment to be in conflict, with the quest for food security coming at huge inevitable environmental costs, ultimately leading to an escalation in land

degradation, a decline in agricultural productivity, and greater food insecurity. The argument effectively states that the world would literally run out of food unless drastic steps are taken to protect the environment from people. Simultaneously, common property tenure systems also exacerbate the use of common property resources, leading to overuse and degradation due to practices such as overgrazing. People (especially the rural poor) have been blamed for misusing the resources at their disposal for short-term gains. Such land misuse is accentuated within the coping strategies employed in the face of food insecurity.

In contrast to the Malthusian view, food security and the environment are considered to be complementary and interdependent, with a healthy natural resource base providing food security. Population increase and income growth are argued to drive technological inventions such as agricultural intensification to solve food production constraints, thus achieving environmental and economical sustainability. It is further argued that the neo-Malthusian perception disregards the potential for economic development within sustainable environments when confronted with rapid population growth, assuming that agroecological zones have limited carrying capacities. Population growth, food security, and a healthy natural resource base are viewed as interdependent and mutually reinforcing for positive gain to both.

Case Study: Machakos, Kenya

Machakos, Kenya, is a case in point with respect to the intertwined nature of population growth, food security, and land degradation. In Machakos, despite a sixfold increase in population over roughly 50 years, there was a fourfold per capita increase in agricultural output while controlling and reversing land degradation of natural resources. While the success of Machakos has been attributed to financial aid and investments, traditional conservation practices such as terracing were made compulsory for agriculture, first by the government then by the farmers themselves. Agricultural intensification occurred in the areas of high population and high land potential, proving that population growth does not necessarily jeopardize the environment.

Land Degradation Impacts on Human Populations

Land degradation as a global development issue directly affects the natural resource base that supports subsistence livelihoods, agriculture, and manufacturing, limiting development opportunities for current and future generations. For example, deforestation and biodiversity loss affect income from tourism and contribute to food insecurity, challenging the eradication of extreme poverty and hunger, the first Millennium Development Goal. Nevertheless, unlike climate change, land degradation is for the most part politically invisible and ignored, with most of the countries that ratified the United Nations Convention to Combat Desertification (UNCCD) not formally addressing it. This inaction in tackling land degradation has resulted in a collective historical legacy from which recovery will be difficult (if not impossible).

Land degradation manifests through various processes including loss of vegetation, soil erosion leading to loss of fertility, deterioration of the physical structure, and loss of soil biodiversity. Also included is soil compaction, which leads to reduced infiltration and increased runoff salinity and sodicity. Downstream effects of degradation processes include water pollution, siltation of watercourses and reservoirs, and loss of animal and plant diversity, leading to loss of ecological function within the affected ecosystem. In turn, land degradation is viewed as a precursor of and a trigger for natural disasters such as landslides.

Globally, land use and land cover changes tend to increase and accelerate land degradation, especially in less developed countries. Land use change has both negative and positive effects on human well-being and on the provision of ecosystem services. Positively, the increase in food and forestry products has resulted in increased income and secure livelihoods for many. Negatively, land degradation, biodiversity loss, and disturbances of biophysical cycles (e.g., water and nutrients) are unfavorable for human welfare in many regions. Reduction in the quality and quantity of ecosystem goods and services through land degradation negatively affects access to material resources, eventually

leading to the inability of people to live lives they value.

The effects of soil erosion, particularly in the tropical regions where the majority of the population resides, could reduce agricultural yields, resulting in increased food insecurity, famine, and poverty, as well as forced migration, especially for impoverished people in poor countries. The demand for more food production may contribute to overexploitation of good agricultural soil and expansion into wooded and marginal areas that are highly susceptible to degradation. Human activities such as clearing of woodlands, logging, firewood collection, and charcoal production lead to deforestation, a component of land degradation. Studies have revealed that the highest rates of deforestation occur in areas where hunger is prevalent.

Land degradation impacts, leading to a possible decline in forest products and wild foods, increase the levels of poverty and malnutrition, especially since these resources are harvested often as coping strategies in the face of droughts, floods, and diseases such as the human immunodeficiency virus and acquired immune deficiency syndrome (HIV/AIDS). Although the poverty and degradation nexus has been a subject of debate, it still is a factor exacerbating land degradation in developing countries.

While agricultural intensification has resulted in more food being produced per hectare than previously, this has been at great environmental costs in the form of loss of habitat and biodiversity, less soil water retention, disturbance of the biogeochemical cycle, increased soil erosion leading to nutrient depletion, salinity, eutrophication, pollution from agrochemicals, and so on. Salinity is induced by irrigation and by the replacement of natural vegetation by crops and pastures that use less water, resulting in increased groundwater infiltration. These processes have led to hazards from floods, dust, pests, and landslides.

Land degradation is acute in mountainous regions, characterized by steep slopes, which allow high rates of soil erosion, and heavy rainfall, resulting in the loss of water retention capacity and conservation, nutrient depletion, and landslides. This problem is exacerbated by the poor and marginalized societies often residing in these areas. Apart from their ecosystem functions,

mountains are home to many unique cultures, which are threatened by the loss of ecosystem services such as water conservation and regulation; provision of food, fuel, and fiber; cultural richness; and diversity. Mountains are also home to significant biodiversity, which may be lost through land degradation. For example, in the United Nations University's Pamir Mountains project sites in Central Asia, the flora contains a unique mix of boreal, Siberian, Mongolian, Indo-Himalayan, and Iranian elements, including at least 5,500 known species of vascular plants, 1,500 of which are endemic.

Degraded lands require more resources to manage them. Poor people do not, however, have the resources due to unfavorable economic returns from agricultural production and poverty, which may constrain rural people from investing in environmentally sustainable practices and soil conservation.

Conclusion

Confronting the complex phenomenon of land degradation requires a global response aimed at increasing the productivity of land ecosystems and making sustainable agricultural production a priority, particularly in view of the urgent need for adaptation to climate change and biodiversity protection. These responses need to take into consideration the multifaceted nature of land degradation and provide solutions that are not only about stabilizing population growth but also include more livelihood options and capacity building through equity in opportunities and the distribution of environmental benefits and improvement in tenure and governance rights, among other factors.

POPULATION AND LAND USE

The neoclassical economic model of population and land use originates from von Thünen's theory of agricultural land use, wherein the "highest and best use" of land depends on the cost of transporting the various crops it can yield to a central marketplace. Because different candidates (crops) have different transport costs—and offsetting market values—those with relatively high (low) transport costs end up being produced close to (far from) the marketplace. So, for example, if tomatoes cost more to transport than wheat, tomato farmers will outbid wheat farmers for locations adjacent to the marketplace.

In the 1960s, William Alonso, Edwin Mills, and Richard Muth (jointly credited but working independently) generalized the Thünen theory of agricultural land use to a theory of modern human settlement patterns. The framework describes a locational rent gradient that falls away from its peak around a business district located at the center of a circular region with a dense transportation network that is situated on an otherwise flat,

featureless plain. At market equilibrium, all households, which are assumed to be identical, attain exactly the same level of "utility" (satisfaction received from consuming a good or service), so the rent gradient reflects the trade-off between location and the cost of travel to and from the central business district. Meanwhile, a corresponding density gradient emerges as a result of households occupying greater amounts of space toward the urban fringe. To maintain a fixed level of utility, households consume more land through substitution with other goods as rent declines. The density gradient, and, with it, development, ends altogether once locational rent reaches zero, and the highest and best use of land is for agriculture or some other natural resource-oriented activity.

Somewhat more formally, the theory underpinning the models of population and land use assumes that households have a common utility function, say $U(z,s)$, which contains a composite good, or numeraire, z , and urban space, or land, s . An individual household's budgetary constraint is determined by its income, y , less the cost of travel, k , between the central business district and its location at radial distance, d :

$$y - k(d) = z + r(d)s,$$

where $k(d)$ is a continuous function that increases with d and $r(d)$ is the locational rent per unit of space at d . Within this framework, households maximize their utility by choosing some combination of the numeraire and land, subject to their particular—spatially explicit—budgetary constraint. The outcome of this choice is a household's bid-rent, $\rho(d,u)$, which is the maximum price it is willing to pay for land at distance d while maintaining a fixed level of utility, u . Simply put, bid-rent is the most that a household's members are willing to pay per unit of space to secure the right to occupy their location of choice, given that they derive happiness from both the land and other forms of consumption. In addition to land prices, bid-rent yields a household's optimal amount of land consumption, or lot size, $\varsigma(d,u)$, which is what ultimately gives the built environment its character (Figure 1).

Figure 1 illustrates how the bidding process translates into a physical pattern of settlement. It displays the marginal rate of substitution, described

Figure 1 The bid-rent process and land use

Source: Carruthers, J. I., Lewis, S., Knaap, G. J., & Renner, R. N. (2009). Coming undone: A spatial hazard analysis of urban form [Electronic version]. *Papers in Regional Science*. Retrieved February 28, 2010, from www3.interscience.wiley.com/journal/122455515/abstract.

by an indifference curve (the *arc*) for a fixed level of utility, u , between the numeraire, z , and land, s , plus the budget constraints (the *dashed lines*) and corresponding consumption bundles (the *dotted lines*) associated with two households located at distances d_1 and d_2 from the central business district, where $d_1 < d_2$. Because the cost of travel to and from the central business district, $k(d)$, is lower at d_1 than it is at d_2 , the net income of the household located at d_1 is greater than the net income of the household at d_2 , or $y - k(d_1) > y - k(d_2)$. The two budget constraints, which must be tangent to the indifference curve for their respective households to each achieve utility level, u , show that (a) the bid-rent, which is equivalent to the slope of the budget constraint, for the household located at d_1 is greater than the bid-rent for the household located at d_2 , or $\rho(d_1, u) > \rho(d_2, u)$, and (b) the optimal lot size for the household located at d_1 is less than the optimal lot size for the household located at d_2 , or $\zeta(d_1, u) < \zeta(d_2, u)$.

In short, households located closer to the center of a region pay a higher price per unit of land and, so, consume less of it by substituting more of

the numeraire than households located farther out. Together, these basic precepts make up the so-called monocentric model of urban form, and they readily generalize more elaborate polycentric models having multiple business districts.

POPULATION DENSITY

Population density is an arithmetic average expressing the number of people, animals, or plants per unit of area for a given spatial unit. For example, Denmark has an average of 121 persons/km² (square kilometer), and the island of Manhattan has 27,267 persons/km². Population density is an important indicator of the ecological relationship between populations and natural resources. In human populations, density has important impacts on the way people live and interact and on the efficiency and environmental impact of their settlements.

Density in Ecology

The defining theme of the science of ecology is the distribution and abundance of organisms—that is, their population densities. Ecologists and biogeographers have developed concepts and methods for the analysis of density patterns applicable to individual animal and plant populations (e.g., species) and to interacting populations within a given area. They have developed and refined the inherently geographical notions of range, carrying capacity, competition for resources, ecological niche, habitat, invasion, succession, and dispersal. Ecologists examine both the effects of environment on animal/plant population densities and the impacts of population densities on the environment (particularly on food resources and competing populations).

Ecological perspectives on density have been applied in anthropology, sociology, and human geography; to examine human evolution and dispersal; to assess the density impacts of hunting, gathering, and agricultural systems; and to study spatial competition and conflict between human groups. The Chicago School of human ecologists (Park, Burgess, and others) applied ecological notions of competition, invasion, and succession to patterns of ethnic and racial groups in large cities.

Global and Rural Population Densities

The term *ecumene* is derived from the ancient Greek word *oikoumene* and refers to the inhabited

(or inhabitable) portion of Earth's surface. This concept relates directly to population density, in that a cutoff density of 1 person/km² (approximately 2.5 persons/mi.² [square mile]) is frequently employed. Below this density level, human groups typically exist as widely scattered hunters, gatherers, or herders and lack permanent settlements. The major nonecumenic areas clearly relate to climate and specifically to areas of desert climate (e.g., the Sahara, outback Australia) or high-latitude areas with insufficient growing seasons for agriculture (e.g., the Canadian north, Siberia). Exceptions occur in the lowland tropics (e.g., Amazonia, interior Africa), where tropical diseases and poor transport access have deterred agricultural settlement, at least until recently. Another low-latitude exception is the Tibetan plateau, which mostly exceeds 4,000 meters in elevation.

The world's major population concentrations were all initially based on subsistence sedentary agriculture, with rural population densities ranging from 25 to 500 persons/km² or more. The three great *islands of mankind* (a term coined by the North American geographer William Bunge) are in East Asia, South Asia, and Europe. After several millennia of agricultural expansion, their limits are now clearly shaped by climate and terrain. Smaller concentrations of more than 25 persons/km² occur in southeast Asia, West Africa, the Central African highlands, and the highlands of Mexico, Central America, and South America. Their limits are partly related to the physical environment, but they are also shaped by factors such as farming technology, warfare, transport access, and disease. Both Edward Ackerman and Ester Boserup have provided authoritative reviews of the environmental, economic, technological, and cultural factors shaping world and regional density patterns.

Rather than using crude (arithmetic) density, population geographers prefer to calculate rural density levels based on the amount of arable land available (variously termed *agricultural*, *physiological*, or *nutritional density*). Factoring in land quality and agricultural practices, the maximum density, or *carrying capacity*, of the land may then be assessed. Though criticized as a crude application of Malthusian thinking, more applicable in biogeography than in human

Figure 1 As shown in this satellite image of Earth's city lights from NASA's Visible Earth project, the brightest areas of Earth are the most urbanized but not necessarily the most populated. For example, compare Western Europe with China and India.

geography, the notion of carrying capacity has recently been recast in the language of environmental sustainability. Overpopulation (unsustainability) is signaled by malnutrition, land degradation, and net out-migration (e.g., the American Dust Bowl of the 1930s or the rice terraces of Luzon today). Conversely, underpopulated regions may have larger landholdings and more prosperous farmers but densities insufficient to develop community ties or to justify the supply of essential government services. National governments have frequently sponsored mass migrations to underused agricultural frontiers to relieve population pressure in their core areas (e.g., the “transmigrations” from Java to Borneo and from the Brazilian Nordeste to Amazonia).

Urban Population Densities

Half the world's population is now urban, and these urbanites live at very high densities on a small fraction of the world's land area. Density is seen as a key attribute of urban life, and owing to its ease of

measurement, it is frequently employed to officially identify and delimit urban and rural areas. For example, the U.S. Census Bureau defines “urbanized areas” as contiguous census units with a minimum population density of 1,000 persons/mi.² and a total population of at least 2,500. Canada uses approximately the same density threshold (400 persons/km²) but a minimum total population threshold of only 1,000. Japan's “densely inhabited districts” are delimited using a density threshold of 4,000 persons/km², reflecting that nation's much higher densities in both rural and urban areas.

Prior to 1900, cities everywhere were compact, and the typical urbanite lived in an apartment or rooming house, at a neighborhood density exceeding 10,000 persons/km². Automobile commuting greatly extended the city and allowed much lower densities. From 1945 until recently, suburban extensions of the North American city typically comprised detached houses at 10 to 15 houses/ha (hectare) of residential land. With about 3.5 people per family, net population densities in these suburbs are 3,500 to 5,000 persons/km², and gross densities

(computed using all the developed land) are only 2,000 to 3,000 persons/km². In “exurban” areas on the rural-urban fringe, the need to separate wells from on-site septic fields keeps lot sizes in the 0.2- to 0.5-ha range, so that the net population densities in subdivided areas fall below 1,000 persons/km².

Urban gross population densities decline from the center toward the periphery for historical reasons (the impact of automobile commuting) and also in response to land value (central land is more valuable and should be used more intensively). Colin Clark demonstrated that the *density gradient* for large cities may be modeled with considerable accuracy by a negative exponential function, and Bruce Newling refined his statistical model to include a central density “crater.” It has been shown that in North American cities the overall gradient has declined through time, peak density levels have declined and moved away from the center, and the central density crater has deepened and enlarged.

Suburban density clusters are a recent feature of urban density patterns. They are typically coextensive with areas of multiple-family housing and are aligned to transit routes. Land use and transport planners have deliberately fostered the development of such high-density clusters and corridors to improve the viability of mass transit and reduce automobile commuting. The policy is known as transit-oriented development (TOD). Planners are also concerned to minimize urban sprawl onto agricultural lands by using a two-pronged strategy: (1) raising density levels in new greenfield developments (“densification”) and (2) reversing the decline of inner-city densities through upzoning and infill development (“redensification”). Not only do such smart-growth policies minimize the size of the urban footprint, but they also support transit usage, reduce greenhouse gas emissions, and reduce the per capita costs of urban services (roads, water supply, sanitary sewers, police, fire protection, etc.).

POPULATION, ENVIRONMENT, AND DEVELOPMENT

Geographers have a long-standing interest in the patterns and processes associated with human population growth and distributions, the impacts of population on the environment, and sustainable development. Human population growth has increased exponentially over the past 150 yrs. (years) and is significantly affecting native ecosystems through the exploitation of freshwater, arable lands, forests, and oceans. There is great interest in addressing these challenges through sustainable development in all world regions.

Population

The world’s population was half a billion in 1650 and reached 1 billion in 1804. By 1927, the population had doubled to 2 billion, and it reached 3 billion in 1959. In 2009, there were 6.8 billion people on the planet, and the world’s population is projected to reach 9 billion by 2050. This rapid increase in human population can be attributed primarily to a dramatic decrease in the death rate, to technological advances, and to migration. The average life expectancy of people in developed countries has increased from 47 to 77 yrs. in the past century, while the average life expectancy in

developing countries has increased from 30 to 55 yrs. Advancements in technology, especially in agriculture due to the Green Revolution (the 1960s), have resulted in greater food availability. The advent of hybrid seeds with a range of environmental tolerance and the use of fertilizers have increased the production of crops, while food distribution methods improved both regionally and globally to satisfy demand. Improved sanitation (i.e., drinking water, waste management) and vaccinations for diseases (e.g., measles and smallpox) have also significantly contributed to the increase in the size of the world's population and in life expectancies. The migration of people to new regions of the world and increases in urban populations have resulted in cities with extremely high population densities over the past 200 yrs., especially in Asia. Indeed, currently, over 50% of the world's population lives in cities.

The world's population and growth rates are not evenly distributed around the globe. Until 1900, most of the world population resided in temperate regions. However, there has been a dramatic increase in the world's population in tropical regions and a significant increase in urban populations in the past 100 yrs. Geographically, Asia comprises 60% of the world's population, Africa 14%, Europe 11%, North America 8%, and South America 6% (Figure 1).

The six most populated countries in 2009 were China with 1.3 billion people, India with 1.2 billion people, the United States with 307 million people, Indonesia with 240 million people, Brazil with 199 million people, and Pakistan with 176 million people.

Models by the World Bank, the United Nations Population Division, and the Population Reference Bureau project population growth to reach a minimum of 9 billion people on the planet by 2100 if couples continue to have children at the current rate. The reason why the world's population is projected to exceed 9 billion to 10 billion people is the momentum built into very young age profiles. For example, half of the population in sub-Saharan Africa or Mexico is below 18 yrs. of age. Couples would have to have only one child for the next 30 yrs. to stabilize at the current levels. This pattern holds true even for countries such as China, which has had a one-child policy since the 1970s (though only enforced in

urban areas), which has resulted in couples having families that are less than replacement size. However, China adds 514,000 new people every month because of the momentum built into the age profile, and it is projected to add another 100 million people by 2050.

There can be no question that the world's population would be higher if it were not for the efforts of national and international public health and family planning organizations. Family planning programs currently focus on local control that is sensitive to cultural beliefs, with an emphasis on access-based contraception distribution, and they primarily target women. Couples in Thailand, South Korea, Taiwan, and China often have just one or two children so that they can provide more prosperity for themselves and their children. Most efforts to lower birth rates through steps such as improving the status of women and providing better education, more social security, and better and more productive jobs result in a higher standard of living.

Environment

The environment includes all living and nonliving things that occur on Earth. The human use of the environment and associated nonrenewable resources have increased significantly over the past 150 yrs. The impacts of population growth on the environment are a function of the numbers of people being added; the income or affluence of the population; the science and technology that sustain populations, especially in urban areas; and the capacity of the environment to provide renewable and nonrenewable resources. However, the exponential growth rate in human population is greatly stressing the world's environmental resources. Human population growth is related to the availability of natural resources such as freshwater, arable land, forests, and fisheries and the quantity of wastes, air pollution (especially in large cities), and greenhouse gas emissions (especially in the United States and China).

As a result of the increase in human population, water pollution and depletion have had a significant impact on fresh water. Water quality in almost all major riverways on Earth is increasingly undrinkable due to increases in sediment,

Figure 1 Global population density (per square kilometer), 1994

Source: U.S. Department of Agriculture, Natural Resources Conservation Service.

human and animal wastes, and agricultural, industrial, and household pollutants. Freshwater lakes have been affected in many regions of the world by increased levels of salt, depletion for agricultural irrigation, and water pollution from sewage. Many freshwater lakes are also undergoing eutrophication due to increased nutrients, which significantly changes the chemical and biological composition of lakes. Aquifers and freshwater lakes in many regions of the world have also been significantly reduced due to the demand for freshwater for agriculture and drinking purposes.

It is currently estimated that 37% of Earth's land surface is covered by agriculture. Three agricultural crops—rice, wheat, and corn—feed a majority of the world's population. Indeed, rice alone feeds two thirds of humanity and provides over 50% of the calories needed for 1.6 billion people to survive. These subsistence crops are generally planted as monoculture in areas with rich soils and low topographic relief. Another environmental impact of agriculture is the increased use of fertilizers and pesticides associated with certain crops. Fertilizers used to increase the yield of annual crops such as sugarcane can be transported to freshwater systems, and pesticides used on crops such as tomatoes and cotton can poison both people and soils. There has been a significant expansion of export crops such as coffee, bananas, and palm oil, which are generally planted as monoculture and have resulted in the conversion of native ecosystems such as tropical forests. The harvesting of timber has also resulted in the conversion of native forests into monoculture plantations of select timber species.

Oceans have been heavily exploited over the past 100 yrs., and global consumption of fish has doubled since 1973. Fishing techniques such as trawling, use of drift nets, and long lining have resulted in the dramatic reduction of densities of most marine mammals, reptiles, and fish. Currently, 32% of the world's fisheries stocks have collapsed, and 39% are overexploited. Other nearshore habitats such as extremely diverse coral reef ecosystems have also been significantly affected. Over one third of the planet's coral reefs, which combined cover an area the size of British Columbia, have been degraded by increased sediment runoff, water pollution, and overfishing.

The extent of human use of ecosystems varies around the globe. Over the past 150 yrs., native ecosystems in Mediterranean climates, temperate grasslands, deciduous forests, and tropical dry forests have undergone great alteration for agriculture, timber production, and urbanization, while other native ecosystems such as tundra, deserts, and tropical rain forests near the equator have remained largely intact. However, in all world regions, there has been an exponential increase in the rates of species extinction and endangerment. Freshwater fish, amphibians, large mammals, and species endemic to islands have been the most adversely affected, and all species could be affected by projected rapid increases in global temperatures.

Development

Development geography is the study of the Earth with reference to the standard of living or the quality of life of the world's people. The Earth can be divided into regions with high human development (e.g., North America, Europe), medium human development (e.g., Asia), and low human development (e.g., West and Central Africa) (Figure 2).

High human development occurs in countries that are industrialized and that have low population growth and infant mortality rates and high per capita income. Low human development occurs in countries with low levels of industrialization, very high population growth and infant mortality rates, and low per capita income. However, the increase in population and natural resource use is currently not sustainable in most regions of the world. There is currently great interest in development and sustainability in all regions of the world to maintain a state in which population and natural resource use rates are sustainable at the local, regional, and global spatial scales. Development has resulted in improved lifestyles and livelihoods for a majority of people in the countries with high human development. However, one-child and two-children families in developed countries burn the most fossil fuels and inefficiently dispose of the most waste. Indeed, the United States contains only 4.5% of the world's population but accounts for 23% of the world's energy consumption, while developing

Figure 2 Three levels of development geography of the world

Source: Retrieved from [http://commons.wikimedia.org/wiki/File:UN_Human_Development_Report_2007_\(1\).svg](http://commons.wikimedia.org/wiki/File:UN_Human_Development_Report_2007_(1).svg) and available from <http://hdr.undp.org/en/reports/global/hdr2007-2008>.

Note: Green = high human development; yellow = medium human development; orange = low human development.

countries such as India contain 18% of the world population and account for only 4% of the world's energy consumption. If everyone in the world had the same level of consumption as the population of the United States, it is estimated that it would take the natural resources and land area of five Earths. Since it is currently not possible for all countries to achieve high development standards without outstripping natural resources, development in general focuses on improving sustainability in countries with high and medium development and increasing the quality of life via food, education, and social justice in low-development countries, where more than 850 million people face hunger and food insecurity.

To achieve these goals of sustainable development, international institutions and governments have tried to address the balance of population growth and natural resource use in ways that reduce the impact of the human population on Earth's natural resources. International institutions, often under the auspices of the United

Nations or the World Bank, have mandated treaties and security arrangements to accommodate and protect the well-being of all sovereign nations. Conferences on improving the status of women, achieving population stabilization, protecting biodiversity, and accommodating the rapid spread of technology have resulted in global charters, regulations, and accords. International treaties such as the Montreal Protocol on Substances that Deplete the Ozone Layer have significantly reduced the release of chemical pollutants that affect the ozone layer, and significant advances have been made via the Kyoto Protocol to the United Nations Framework Convention on Climate Change to address issues of global warming and climate change. There has been progress on the enforcement of population and environmental treaties related to deforestation, protection of biodiversity, and the law of the seas, though much more is needed.

Within countries, environmental legislation, incentives, and enforcement are important tools

for working toward sustainability at regional and local spatial scales. Several geographical tools, such as censuses, geographic information systems, and satellite imagery, can be used for monitoring and assessing the status of populations and the environments as related to sustainable development. Although stabilizing human population growth and sustainable development of Earth's natural resources are still significant challenges that current and future generations will have to face, there have been significant advances in ideas and policies over the past 50 yrs. to meet these global challenges.

POPULATION GEOGRAPHY

Population geography asks two basic questions about the distribution of people, namely, "Where?" and "Why there?" In other words, population geography is specifically concerned

with the geographic distribution of people, their composition in terms of age and gender, and the three main processes that determine an area's population growth, namely, fertility, mortality, and migration. While the boundary between population geography and demography has become blurred, population geographers contribute significantly to population studies and/or demography in their own unique way by offering a geographic perspective to the study of population.

While demographers measure and analyze demographic data with an emphasis on time, historians trace the evolution over time of such data, and sociologists seek the causes of the trends in demographic analysis and their repercussions on societal processes, population geographers focus on the characteristics of population distributions that change in a spatial context and why those changes take place. The population geographer uses geographic tools and techniques such as population density maps and hatch, choropleth, isoline, and dot maps to show the ways in which factors of population change such as fertility, mortality, and migration are distributed in space and attempts to explain those distributions by a careful examination of the underlying processes. In short, population geography can be defined as a systematic and regional analysis of area patterns of population distribution, composition, migration, and growth, as well as their causes and the effects they have on cultural and economic landscapes. This entry briefly examines the roots and growth of population geography, the contents of population geography, and its future prospects.

Roots and Growth of Population Geography

The benchmark in the development of population geography is often cited as the 1950s, after Glenn Trewartha gave his presidential address in 1953 to the Association of American Geographers. However, the roots of population geography can be traced back several centuries earlier. While Trewartha's address was a defining moment in the development of population geography as a subdiscipline of geography, there were before him others who had been working in this field elsewhere, particularly in Germany, France, Britain,

and Russia. These precursors to the modern subdiscipline of population geography concentrated on the examination of population statistics, population mapping, and the study of human elements in geography.

By the 1800s, the discipline of geography had experienced great improvements in its methods, such as the introduction of statistical methods, quantitative indices, and better cartographic techniques. These improvements required the existence of high-quality data, which were in short supply at that time. Thus, geographers and cartographers throughout Europe, and particularly in Germany, banded together to begin compiling and evaluating different sources of quantitative data. The leading geographic and cartographic center was the Geographische Anstalt Justus Perthes in Gotha, Germany. These data were then used to compile maps that depicted, among other things, the sizes of settlements with respect to their population. These early private efforts at compiling data were then taken up by the League of Nations and later the United Nations and the member states of these institutions. However, the seeds of population geography had been sown in these early periods, and to this day, geographers continue to supplement government statistics by gathering their own population data during field investigations.

With the growing availability of population-related data, population geographers perfected their mapping techniques to show global and local population distributions. While this topic continues to remain the central focus of population geographers, other population characteristics were also being mapped as early as the 1820s. For example, maps of literacy, crimes, and marriages in France and England appeared during the 1820 to 1870 period. During the interwar years, European geographers concentrated on producing population maps at national or continental levels, with special reference to Europe. Many of these maps attempted to portray the localities of different ethnic groups in Europe. This preoccupation with generating population maps went on well into the 1960s. In short, population maps have a long history, dating back from the 1800s to the present-day global, national, and regional atlases.

The third important development that contributed greatly to the development of population

geography as a subdiscipline of geography was the development of human geography. Friedrich Ratzel is usually credited with establishing this subdiscipline of geography in Germany, which he termed *Anthropogeographie* in 1842. Although Ratzel is depicted as the founder of the environmental deterministic school in geography, he brought into the limelight the study of population and its characteristics and the relationship between people and their environment and how the two interact to shape each other. The French school of thought (*geographie humaine*) in the late 19th century also contributed greatly to the growth of human geography. This school espoused a more moderate approach to the interpretation of human-Earth relationships and succeeded in redirecting other geographers to the study of population and its characteristics and impact on the environment.

Although the roots of population geography go back to the 1800s, it was not until the 1950s that the term *population geography* came into vogue. Many credit the emergence and recognition of population geography as a new field within geographical studies to the influential statement of Trewartha in 1953. In his presidential speech to the Association of American Geographers in 1953, Trewartha noted that population geography had been a neglected aspect of the discipline of geography. He pointed out that population was a pivotal element in human geography and that its continued neglect would seriously affect the development of the discipline. Initially, the response by geographers to Trewartha's clarion call was lukewarm, and it took years for this subbranch of geography to develop into what it is today.

Between the 1950s and 1960s, other developments occurred that gave impetus to population geography. For example, the tremendous proliferation of population data since the 1950s with the formation of the United Nations and the regular census taking by most countries provided pertinent data on births, deaths, mobility, marriages, divorces, and so on. The rise of demography to a separate discipline in the 1950s also had a stimulating impact on the rise of population geography. Demography has developed a rich body of highly sophisticated methods for population analysis, which greatly enriched research in population geography and the wider field of

population studies. The rapid growth of the global population since the end of World War II heightened the need to examine population issues closely. Geographers, demographers, and other scientists began to wonder about the implications of rapid population growth on food and nutrition, deforestation and habitat destruction, air and water pollution, depletion of energy and mineral resources, and other social, economic, and environmental ills.

It was not until the appearance of several influential textbooks on population geography in the mid 1960s that this component of geography became recognized as a full-fledged component of the discipline, a component that could offer fruitful avenues of research and teaching. These books included Pierre George's *Géographie de la population*, published in Paris in 1965; John Innes Clarke's *Population Geography*, published in 1965; Jacqueline Beaujeu-Garnier's *Geography of Population*, published in 1966; and Wilbur Zelinsky's *A Prologue to Population Geography*, published in 1966. These textbooks offered a major stimulus to the emergence of the discipline of population geography. Although none of these books by themselves succeeded in comprehensively covering the content of population geography, together they offered a holistic treatment of the content and methodology of population geography, which at this early point in time was concerned with the distribution of population and understanding the geography of a wide range of population phenomena.

Since then, a number of influential textbooks on population geography have appeared in North America, Europe, and elsewhere in the world. For example, in North America, two influential textbooks on population have endured the test of time: Gary Peters and Robert Larkin's *Population Geography: Problems, Concepts and Prospects*, first published in 1979 and now in its 8th edition, and John Weeks's *Population: An Introduction to Concepts and Issues*, now in its 10th edition. Weeks's book illustrates the synergy and blurring of boundaries between population geography and demography in North America and is widely used in population geography courses as well as demography courses, bringing in the much needed cross-fertilization between the two disciplines. Indeed, demography and population

geography are concerned with the same subject matter, namely, the study of human populations. Both disciplines are quantitative in their approach and rely heavily on statistical data. However, in spite of the blurring of subject material and approaches between the two fields, the main difference is that demographers continue to place emphasis on time, whereas geographers emphasize analysis using geographic units or space as the major vehicle within which to place population characteristics.

Population Geography Courses

Population geography has become well entrenched in many departments of geography at institutions of higher learning, particularly in North America and Europe. The content of such courses has been shaped by the recognition that the scientific study of human populations is an interdisciplinary endeavor that involves disparate disciplines, including demography, sociology, anthropology, psychology, political science, economics, biology, and others. However, the three main components or processes of population change remain central to the content of population geography syllabi. These are fertility, mortality, and migration.

In population geography syllabi, these three components form the basis for an examination of more specific topics, such as sources of population data, population growth and change, population structure/composition and spatial distribution, theories of population change (e.g., the Malthusian and Marxist perspectives and demographic transition theory), population processes (e.g., patterns and trends in fertility and mortality, migration and mobility), and the relationships between population on the one hand and the environment, food supply, and other socioeconomic factors on the other.

Much of this content goes back to Trewartha's vision for population geography, in which he viewed a discipline that was more systematic in its treatment of population. Trewartha essentially advocated a descriptive approach that was to include other aspects of population such as social, cultural, and economic characteristics. His vision saw the study of population geography being divided into three main areas of research, namely, historical population geography, population

numbers, and qualities and regional distribution. Historical population geography would examine the regional variations in population growth and decline over time, while population numbers would examine gross patterns of numbers, fertility and mortality dynamics, population density, and migration. Regional population geography would examine population characteristics such as race, nationality, sex, age, health, and other socio-economic characteristics such as religion, education, occupation, family structure, urban/rural residence, and cultural customs. The unifying factor for the three areas of inquiry and teaching was to be the region. While Trewartha emphasized systematic description in his vision of population geography, other scholars have refined his vision to broaden the field to an examination of dynamic rather than static spatial processes. Although the methods of approaching the study of population geography have changed over time, the substantive topics outlined by Trewartha continue to form the basis for population geography today.

Research Foci in Population Geography

Population geographers have been active in research and publications. Their geographic approach offers the spatial perspective that examines population variables cartographically (via the use of maps and now geographic information systems) and/or statistically in an attempt to examine the underlying factors that explain the exhibited spatial patterns of the variables, be it fertility, mortality, or migration. Two main phases of research foci can be discerned, namely, the 1950s to 1970s and the 1980s to 1990s.

During the 1950s and 1970s, research in population geography concentrated on the examination of four topic areas. The first was the description of demographic structures in geographic space using empirical and positivist approaches. Population geographers believed that to create scientific knowledge about demographic structures in space, there was a need to produce the evidence through field observations and descriptions of population phenomena. Through the positivist approach using the scientific method, the empirically observed trends would lead to the affirmation or negation of hypotheses. The observed patterns were summarized via the use of maps

and quantitative methods, many of which were being developed in the discipline of demography. Topics of research in this area included population concentration or dispersal, population density, urban population segregation, population flows, and so on. The second area of research was describing demographic change via the use of the population balancing equation and spatial demography. A good example here is the tracking of the centroid of the U.S. population over time and in space. The third area was explaining demographic changes in space and in time, such as age-sex distributions, population growth, and the major variables of population change, fertility, mortality, and migration. Using positivist and empirical approaches, population geographers contributed significantly in the areas of demographic transition theory and theories of migration. One of the greatest contributions of population geographers to population studies was a greater understanding of migration and the forces that cause people to move.

The 1980s and 1990s saw both continuity and critical reflections on population geography's research directions. During this period, research in population geography focused on four main areas, with migration dominating the volume of research. While research on migration differentials, migration systems, and regional and international migration continued, population geographers began to engage in critical debates about the geopolitics of mobility, the racialized and gendered nature of migration, immigrant labor markets, and so on. The other three areas of research focus included issues of reproduction and health inequality, the implications of aging, and population and the environment. In the post-September 11, 2001, period, population geographers have been moving into new areas of research, such as population movements as they relate to national security, neoliberalism, the transnational migrant in an era of globalization, and geopolitics.

The Future of Population Geography

Population geography has done well over the past 50 years. From its inception, it experienced steady growth and development, with undergraduate and graduate-level courses being developed at colleges and universities in Europe, North

America, and elsewhere. The elevation of population geography to one of the official specialty groups within the Association of American Geographers in the 1970s meant its acceptance as a significant part of geography.

In spite of these successes, population geographers began to be critical of their discipline and to cast self-doubt on population geography's effectiveness and contributions to scientific and social inquiry. Two main contending camps appeared on the scene. The first advocated maintaining the status quo, arguing that the discipline was sound and did not need to be tampered with. The second camp wanted population geography to expand its methodologies and approaches to include other perspectives and be more conceptually inclusive. The argument here was that population geography should not solely rely on empirical and positivist approaches in research but rather adopt a mixed- and pluralistic-methods approach. What, for example, were the boundaries between population geography and other fields such as medical geography, spatial ecology, demography, and population studies? The launch in 1995 of the *International Journal of Population Geography* and its subsequent change in name in the mid 2000s to *Population, Space and Place* brought into sharp focus these divisions. The broad coverage and the publication of six issues a year appears to have favored those in favor of a pluralistic coexistence within the field. Indeed, this journal is advertised as offering an energetic forum to debate, inform, and review the latest developments in areas such as population and society, fertility, mortality and migration, quantitative and qualitative methods of population analysis, aging populations, census analysis, spatial demography, population policies, theory and population, population distribution and change, and population and development.

The pluralist approach in population geography appears to be the future trajectory of this subdiscipline. This notion implies the existence of a varied group of population geographers who are committed to interrogating population issues using varied methodologies and theoretical approaches. Indeed, a good number of population geographers are deploying new theoretical approaches that go beyond positivist and empirical approaches. Today, research using approaches

such as social constructivism, poststructuralism, postcolonialism, and structuration theory is becoming common in population geography.

POPULATION PYRAMID

Except for total size, the most important demographic feature of a population is its age-sex structure. The age-sex structure affects the needs of a population as well as the supply of labor; therefore, it has significant policy implications. A rapidly growing population implies a high proportion of young people under the working age. A youthful population also puts a burden on the education system. When this cohort enters the working ages, a rapid increase in jobs is needed to

Figure 1 Population pyramids for developing countries typically exhibit a wide base, reflecting high fertility rates, while those in economically developed parts of the world portray a population more evenly distributed across age groups.

accommodate it. In contrast, countries with a large proportion of older people must develop retirement systems and medical facilities to serve them. Therefore, as a population ages, its needs change from schools to jobs to medical care.

The age-sex structure of a country or region can be conveniently summarized or described through the use of population pyramids. They are divided into 5-year age groups, the base representing the youngest group, the apex the oldest. Population pyramids show the distribution of males and females of different age groups as percentages of the total population. The shape of a pyramid reflects long-term trends in fertility and mortality and the short-term effects of “baby booms,” migrations, wars, and epidemics. It also reflects the potential for future population growth or decline.

Two basic, representative types of pyramid may be distinguished (Figure 1). One is the squat, triangular profile. It has a broad base, concave sides, and a narrow tip. It is characteristic of

developing countries having high crude birth rates, with a young average age and relatively few elderly. Natural growth rates in such societies tend to be high.

In contrast, the pyramid for economically developed countries, including the United States, describes a slowly growing population. Its shape is the result of a history of declining fertility and mortality rates, augmented by substantial immigration. With lower fertility, fewer people have entered the base of the pyramid; with lower mortality, a greater percentage of “births” have survived until old age. In short, the structure of the population pyramid closely reflects the stage of the demographic transition in which a country is positioned.

PORTOLAN CHARTS

Portolan charts were produced in Mediterranean lands primarily during the 13th through 16th centuries. Originally single-sheet maps that were drawn on rolled scrolls of sheepskin and used by sailors in the Mediterranean region, they were soon joined by portolan atlases that typically covered the Atlantic coast of Europe and the Black Sea as well as the Mediterranean and that likely served a more decorative function. In both formats, however, portolan charts are striking for their relatively “modern” appearance and their apparently accurate representation of coastlines, leading the early 20th-century cartographic historian Charles Beazley (1904) to call portolan charts “the first true maps” and to assert that “in them, true cartography, the map-making of the civilised world, begins” (p. 161).

Perhaps the most distinctive feature of the portolan chart is the network of rhumb lines—usually colored red, green, and/or brown—that cross over ocean space and in some cases continue across land space. Together with a portolan—a list of directions for sailing from one port to another along a coastline—these rhumb lines were used for navigation. For instance, a sailor wishing to cross the Mediterranean could find his source and destination cities on the portolan chart, note the rhumb line whose angle corresponded to the angle of a line drawn between the two cities, determine the corresponding compass heading, and then sail by dead reckoning along that heading until he reached the opposite coast. On reaching the coast, assuming that the boat did not land precisely on target, the sailor could use an accompanying portolan to navigate coastwise to reach his ultimate destination.

Portolan charts also are notable for their simplistic projection, in which longitude lines are drawn as straight, parallel lines without any

compensatory adjustment in the spacing of latitude lines (e.g., as is achieved in a Mercator projection). This projection, and the accompanying system of navigating by dead reckoning along a compass heading as one traversed a conceptually placeless ocean, was suitable for trans-Mediterranean travel, where north-south distances are relatively small, currents and tides are minor, magnetic variation is insignificant, and storms are rare during the sailing season. However, attempts to transfer this projection and its corresponding technique of navigation to longer-distance ocean voyages would be disastrous, and thus, it seems likely that the frequent presence of rhumb lines on 17th-century world maps was purely decorative or, perhaps, was intended to reference an earlier era of Mediterranean voyaging.

Despite the break between the navigational practices enabled by and reflected in the portolan chart and those in later maps, some scholars have noted that portolan charts nonetheless embody a perspective that prefigures modern conceptions of territory and mobility. As on a modern map, the ocean on a portolan chart is typically devoid of emotive, natural, or human signifiers (e.g., sea monsters, ships, toponyms). Instead, the ocean is represented as an empty space that can be rationally crossed by sailors following geometric logic and the natural law of magnetic north. In this sense, the portolan chart established the norm of the ocean as an easily crossable but empty (or non-exhaustible) and hence nonpossessable space, which was later to be codified by 17th-century jurists such as Hugo Grotius and which has gone on to inform the modern law of the sea. Likewise, the coastline on portolan charts is represented as a series of destinations (names written along the coastline) whose social significance is buttressed with numerous flags. Here, too, a modern norm is prefigured, as civilization is associated with naming and political territorialization. Behind the coastline, the interior—especially on Iberian portolan charts—is depicted as a fecund space of opportunity, filled with bustling human settlements and exotic nature, prefiguring a colonial mindset where the interior of distant lands—the space to be encountered *after* an ocean voyage—is presented as inaccessible yet ripe with opportunity (as well as dangers). Finally, islands on portolan charts are represented as territorially unified entities wherein

the seemingly incontrovertible boundary between land and sea is used to naturalize a political boundary between the internal space of the state and the outside space beyond its control. This depiction foreshadowed the ideal of the territorial state that was to become a political (and cartographic) norm on land in the centuries that followed.

In short, while Beazley might well be accused of ethnocentrism in his identification of certain maps as being “true” and in associating them with a singular “civilization,” his broader point—that the spatial conceptions inscribed in the portolan chart foreshadowed perspectives on space that were to inform emergent systems of exploration, colonialism, and merchant capitalism—is well taken. Long celebrated for their beauty and “accuracy,” portolan charts should also be appreciated for the ways in which they inscribed ideas about divisions between fixity and movement, land and ocean, and territory and an external space that is

immune to possession. These idealized divisions, expressed so succinctly in the portolan chart, went on to guide the spatiality of the modern era.

PORTS AND MARITIME TRADE

The enduring characteristic of maritime transportation is its ability to move large quantities of cargo over long distances. This activity is shaped by the maritime geography of the world, mainly the configuration of oceans, coasts, seas, lakes, and rivers. Where possible, the construction of canals, channels, locks, and dredging have facilitated maritime circulation and reduced the discontinuity imposed by geography.

A Fundamental Role in Global Trade

Maritime transportation is as old as global trade, and historically, the scope and extent of long-distance trade were determined by developments in maritime transportation technology. Between the 16th and 19th centuries, the galleon was the linchpin of long-distance colonial trade, and the refinement of sailing technology led to fast clipper ships in the mid 19th century, which essentially reflected the optimal in wind-propelled maritime technology. Clipper ships were, however, short-lived and were supplanted by steamships, which led to a remarkable specialization of ship function with liners, battleships, cargo ships, tankers, and container ships, to name just a few. Yet the role of maritime transportation in the movement of passengers is marginal; it is almost exclusively the domain of freight. International trade and seaborne trade are thus interrelated. In 2006, seaborne trade accounted for about 90% of global trade in terms of volume and 70% in terms of value.

Maritime transportation rests on the existence of regular itineraries, better known as maritime routes. They draw arcs on Earth's water surface, as intercontinental maritime transportation tries to follow the great circle distance. Maritime transportation operates in a space that is at the same time geographical with respect to its physical attributes, strategic by virtue of its military importance, and commercial in its usage. While geographical considerations tend to be constant in time, strategic and especially commercial considerations are much more dynamic. For instance, strong industrial growth in Pacific Asia has been accompanied by a surge in port activities along the Chinese coast as well as growth along trans-Pacific and trans-Indian Ocean shipping routes.

Shipping has traditionally faced two drawbacks. It is slow, with speeds at sea averaging 15 knots (26 kilometers per hour). Second, delays are encountered in ports where loading and unloading take place. The latter may require several days of handling when break-bulk cargo (that which is not containerized) is involved. These drawbacks are particularly constraining when goods have to be moved over short distances or when shippers require rapid service deliveries. However, technical improvements tend to blur the distinction between bulk and break-bulk cargo, as both can be unitized on pallets and increasingly in containers. For instance, it is possible, and increasingly common, to ship grain and oil, both bulk cargoes, in containers. Maritime shipping is dominated by bulk cargo, such as petroleum, minerals, and grains, which combined account for roughly 70% of total ton-miles shipped. These flows supply the world's energy generation, manufacturing, and food transformation systems. The share of break-bulk cargo is decreasing steadily, mainly because of containerization. Consequently, the amount of containerized freight has grown substantially, and the majority of the global shipment of manufactured goods is now carried in containers; the 20-foot-equivalent unit, or TEU, is a common measure of volume.

Ports: Valuable Resources

Although the physical geography of the world conveys a staggering amount of coastline, only a limited amount is effectively suitable for port operations. Port terminals handle more freight

than all other types of terminals combined. To perform their role, port infrastructures jointly have to accommodate transshipment activities both on ships and on land. They are points of convergence between land transport and maritime systems. Considering the operational characteristics of maritime transportation, the location of ports is constrained to a limited array of sites, mostly defined by geography. Most ports, especially those that are ancient, owe their initial emergence to their site, as the great majority of harbors take advantage of a natural coastline or a natural site along a river. The suitability of port sites continually changes with technical changes in maritime shipping and coastal urbanization. Such sites have become valuable and rare resources.

A Matter of Scale

The principle of economies of scale is fundamental to the economics of maritime transportation because the larger the ship, the lower the cost per unit transported. This trend has particularly been apparent in bulk and containerized shipping. For instance, the evolution of containerization, as indicated by the size of the largest available containership, has been a stepwise process (Figure 1). Changes are often rather sudden and correspond to the introduction of a new class of containership. Since the 1990s, two substantial steps took place. The first step involved a jump from 4,000 to 8,000 TEUs, effectively moving beyond the “Panamax” threshold. This threshold is particularly important, as it indicates the physical capacity of the Panama Canal and thus has for long been an important operational limitation in maritime shipping. The second step took place in the 2000s, as the maximum size reached the 13,000- to 14,000-TEU level. This is essentially a “Suezmax” level, or a “new Panamax” class, that is, the largest size of ship that will be able to pass through the expanded Panama Canal after it is completed in 2014. From a maritime shipper’s perspective, using larger containerships is a straightforward process, as it conveys economies of scale and thus lowers costs per TEU carried. From a port terminal perspective, such ships bring intense pressures in terms of infrastructure investments, namely “portainers.” Thus, the matter of economic scale leads to a paradox—the greater

the economies of scale applied to maritime shipping, the smaller the number of ports that are able to handle such ships.

Maritime Gateways and Hubs

The current geography of ports and maritime trade has been the most transformed by containerization, since it permitted an entirely new class of ships, new companies (or the transformation of existing companies), new port locations, new networks, and new flows.

For a long period, the world’s most important ports were North American (e.g., New York) and Western European (e.g., Rotterdam). Containerization completely changed the world’s commercial geography with the emergence of an array of new port locations (Figure 2). This geography indicates a high level of traffic concentration around large port facilities, the top ones being Pacific Asian ports along the Tokyo-Singapore corridor. As export-oriented economic development strategies took shape, the number of containers handled in Pacific Asian, notably Chinese, ports surged in volume. There is also an emerging geography of container ports characterized by a specialization in which some act as gateways and some as hubs. Gateway ports command the access of large manufacturing or market regions. Hong Kong, Los Angeles, and Rotterdam are notable examples. Hub ports (or offshore hubs) act as intermediary locations where containers are transhipped between different segments of the global maritime transport system. Singapore and Dubai are among the most prominent.

The conventional bulk shipping network is point-to-point, with two ports directly serviced and with the ship coming empty for the backhaul (the return voyage to the port of origin). This system typically reflects the pattern of oil, mineral, and grain shipping, with origins corresponding to extraction regions and destinations being large, urbanized regions. Containerized shipping permitted the emergence of new networks, namely, pendulum services. They involve a set of sequential port calls along a maritime range, commonly including a transoceanic service from ports in another range and structured as a continuous loop. Their purpose is servicing a market by balancing the number of port calls and the frequency

Figure 1 The largest available containership, 1970–2007 (in TEUs [20-foot-equivalent units])

Source: Data compiled by Jean-Paul Rodrigue and T. Notteboom.

of services. For instance, pendulum services between Asia and Europe have on average 8 to 10 containerships assigned and involve 8 to 12 port calls. Most transatlantic pendulum services have 6 to 8 containerships and involve 6 to 8 port calls. A pendulum service is fairly flexible in terms of the selection of port calls, particularly on maritime ranges that have nearby and competing ports grouped as regional clusters (e.g., the North American east coast, Western Europe). This implies that a maritime company may opt to bypass one port to the advantage of another if its efficiency is not satisfactory and if its hinterland access is problematic. The shipping network consequently adapts to reflect the changes in market conditions.

The global shift in the location of manufacturing activities as well as changes in supply chain management have led to new flows of maritime shipping. Flows of raw materials handled by maritime shipping have adapted, and emerging manufacturing clusters have seen significant growth. However, new flows are mostly evident

in patterns of container shipping. As exemplified by Figure 2, the new geography of production entails a new geography of distribution and its related flows. Because of a global trade structure characterized by imbalances, this structure implies its own new sets of flows. Many containers are moved empty, generating no income but carrying a cost that must be assumed in one way or the other. Either full or empty, a container takes the same amount of space on a ship or in a storage yard and takes the same amount of time to be transhipped. For instance, there are three times as many full containers moving from Asia to the United States as there are from the United States to Asia. In 2005, about 70% of the slots of containerships leaving the United States were empty, with major container ports such as Los Angeles handling large amounts of empty containers. Other major maritime trade routes, such as the Asia-Europe segment, are facing a similar but less acute imbalance. Thus, production and trade imbalances in the global economy are clearly

Figure 2 Traffic at the 50 largest container ports, 2006

Source: Containerization International. Cartography by author.

reflected in imbalances in physical flows and transport rates. For trans-Pacific trade, it costs more per TEUs for eastbound flows than for westbound flows, making freight planning a complex task for container shipping companies. For Asia-Europe flows, westbound rates are higher than eastbound rates.

Maritime Shipping Companies and Port Operators

The maritime transport industry is one of the most globalized industries in term of ownership. Maritime shipping companies and the majority of the largest port terminals are privately owned or operated. Such large assets must be efficiently managed, which entails extensive capital requirements. The trend in recent years has been a convergence

between the maritime segments of global trade and inland freight distribution. Global port operators, such as APM (Denmark), DPW (Dubai), HPH (Hong Kong), and PSA (Singapore), have been active in acquiring a portfolio of terminal assets in almost all the major ports of the world. Some, such as APM, are a direct subsidiary of a maritime shipping company—Maersk, the world's largest, in this case. Thus, a growing convergence between maritime shipping, ports, and inland operations enables large private conglomerates to achieve a level of control over global supply chains. This is particularly important as global trade is more than a matter of capacity; it is also concerned about the timeliness and reliability of the distribution.

The emergence of global private operators marks a reversal in the trend of considering ports to be

public entities, since many became inefficient and unable to cope with market pressures. The top five terminal operators account for about half of the world's port container throughput. In an era characterized by lower levels of direct public involvement in the management of transport terminals, specialized companies involved in the management of port terminals are finding opportunities at the global level. They tend to be horizontally integrated entities focusing on terminal operations in a variety of locations. The main tool used by global port operators to gain control of port terminals has been concession agreements. A concession agreement is a long-term lease involving the requirement that the concessionaire undertakes capital investments to build, expand, or maintain the cargo-handling facilities, equipment, and infrastructure. The range of port terminals controlled by port holdings covers several of the largest freight markets. As globalization permitted the emergence of large multinational corporations managing assets in a variety of locations, global port holdings are a similar trend concerning the management of port terminal assets. This has been a very profitable business, with substantial positive impacts in the efficiency of ports and maritime trade.

POSITIONALITY

Positionality is the notion that personal values, views, and location in time and space influence how one understands the world. In this context, gender, race, class, and other aspects of identities are indicators of social and spatial positions and are not fixed, given qualities. Positions act on the knowledge a person has about things, both material and abstract. Consequently, knowledge is the product of a specific position that reflects particular places and spaces.

Issues of positionality challenge the notions of value-free research that have dismissed human subjectivity from the processes that generate knowledge and identities. Consequently, it is essential to take into account personal positions before engaging in research, especially qualitative research. Consideration of the positioning of those engaged in the production of knowledge reveal that research is always and inevitably shaped by the actions and values of the researcher. Therefore, truly value-free research, if not impossible, is at least nearly impossible to obtain; the researcher's circumstances of life, his or her personal beliefs, and the mere fact of being a member of a society position the researcher in specific places and spaces and shape his or her values, assumptions, priorities, and ethics. This notion makes the idea of having an independent position from which one can freely and fully observe the world or be detached from the circumstances taking place in the research arena particularly unlikely.

Confronted with issues of positionality, scholars and researchers have responded in different ways. One strategy that attempts to address the issue of positionality in the context of conducting research is the use of the third person in reports, notes, interviews, questionnaires, and other research-related manuscripts. For researchers, writing in the third person aims to establish an outside view and a detached position, and therefore an objective tone. However, this practice has been frequently criticized. From the critic's standpoint, writing is much more than a set of facts or statements, because it also deals with representing and interpreting the researched subjects. In that context, each work affiliates itself with other works and with specific groups and institutions, and in doing

so, such works and positions can create not only knowledge but also the reality that they consciously or unconsciously seem to describe. Consequently, every author must locate herself or himself in what she or he writes and be aware of the kind of narrative voice, images, themes, and motifs adopted in her or his text. This is not simply a problem of finding a position but also the question of selecting which texts are the ones best suited for the research. In this notion, location is as important as awareness of personal positions. There is a strategic location that describes the author's position in a text, but there is also a strategic position that analyzes the way in which different modalities of the text (i.e., symbols used in the text, types of text, and textual genres) materialize among themselves and thereafter in the culture at large.

Another strategy researchers use to acknowledge their positionality is self-criticism. Scholars and researchers use self-criticism to locate biases of both inclusion and exclusion. In this context, researchers dismiss the notion of value-free research and recognize that claims to objectivity and neutrality serve only to make biases and human subjectivity invisible. Making the researcher's biases visible through a self-reflexive understanding of his or her positioning and fieldwork relations can help the researcher avoid invalid generalizations. This approach requires a commitment to understanding how the values and subjectivity of the researcher are part of the construction of knowledge.

These issues of positionality suggest that there is always a relationship between the researcher and the researched. This relationship deals with power and interpretation, as the researcher is in the position of interpreting the lives of others. From this perspective, it is essential to draw attention to the ways in which representations do not merely reflect social reality but are also constitutive of it. The politics of positionality demand that attention be paid to the structures of power that privilege certain voices while silencing others and endorse some points of view while dismissing others. In other words, researchers cannot ignore the problematic nature of what representation involves. As part of an in-depth self-reflection, one must know how to position oneself before drawing the line that makes the distinctions between "us" and "them." Positionality is not just acknowledging personal positions; it also

involves understanding how labels (such as race, ethnicity, and gender) are being constructed and represented through judgments made with the purpose of "othering." Therefore, no production of knowledge can ever dismiss or disclaim its author's involvement and positionings.

To be effectively self-reflective and fully locate themselves in their research, it is essential that researchers understand the differences between the positions of insider and outsider. Sharing the same background or similar identity, having things in common, or simply having an affinity with the researched subject(s) can influence the research outcomes. On the one hand, such insider positions can facilitate the collection of data, communication, movement, and so on. On the other hand, such a position can be somewhat problematic, as personal positions can restrict the development of the research by providing only a partial view and by not allowing the researcher to reflect on views that are opposed to her or his own. Likewise, failure to understand the differences between positions as insider and outsider can misdirect the potential research results, the production of knowledge, and the formation of identities. Nevertheless, given the difficulty involved in the task of completely understanding the self, it may be virtually impossible to be completely self-reflexive and fully aware of self-positionings.

POSTCOLONIALISM

Postcolonialism is a vast and diverse area of study that seeks to examine the experiences of peoples and places—colonized and colonizers alike—both during and following the period of formal colonialism. By using postcolonial theory, postcolonial studies attempt to lend voice to the colonized and offer alternative interpretations of the process of colonization and the experiences of colonialism and empire. They also seek to challenge the naturalized assumptions of Western power and knowledge while creating space for alternative (and equally valid) knowledges and power dynamics.

While postcolonial studies originated in the fields of literary and cultural studies, they have since become interdisciplinary engagements that bridge the humanities and social sciences, including human geography. This entry offers an overview of the various meanings of postcolonialism, postcolonial theory, postcolonial studies, and postcoloniality, followed by an exploration of the historical development and critiques of postcolonialism. These include the critique of postcolonial representational analyses' immateriality, the debatable strength of real-world applicability of postcolonial critiques, and the question of the real beneficiaries of postcolonial destabilizations. It concludes with an examination of the subfields within geography that have employed a postcolonial framework.

Postcolonialism's breadth has aided in the development of multiple, sometimes hotly debated forms of the term *postcolonialism* itself. In a very basic and literal sense, postcolonialism refers to the period of time following colonialism, or the postindependence time period. However, this simplified notion ignores the continued connectivities, dependencies, exploitations, and forms of neo-imperialism that persist between the formerly colonized states and their former colonizers. The

"post" in "postcolonialism" suggests that the era is finished, but as many scholars have pointed out, postcolonialism (like other "posts") might be better viewed as a process of alteration with lingering colonial links. Postcolonial theorists actively work toward achieving more accurate and sensitive historiographies and representations, an equitable distribution of resources, and a rethinking and restructuring of Western knowledge production. However, to assume that such a goal has ever actually been, or ever will be, achieved is misguided.

Scholars working on postcolonialism use *postcolonial theory* to refer to the wide range of ideas that form the core of postcolonial studies. The works of foundational thinkers such as Edward Said, Homi Bhabha, and Gayatri Spivak, among others, have been particularly central to the field. Postcolonial studies have used these theories in a variety of ways, from work on political economy to identity and sport studies. *Postcoloniality* refers to the condition of living in a period of time after colonialism. This incorporates everything from material conditions, including the frequently unequal distribution of resources, to the less material realms, such as the ways in which newly independent peoples perceive their own identities. In addition to the creation of new words, postcolonial scholars have also debated whether or not the word *postcolonialism* should be hyphenated and even whether the single word *postcolonialism* does justice to the multiple, varying postcolonialisms in existence throughout the world.

Historical Development

Edward Said's *Orientalism* (1978) is frequently cited as the most influential work in the rise of postcolonial theory. Said employed a Foucauldian framework to critique Orientalist discourse, exposing the ways in which "the West" represented "the Orient" as barbaric, irrational, and "Other." Part of Said's influence on postcolonial theory has been to encourage a continued focus on the critique of discursive representations. Investigations of textual representations within colonial and postcolonial discourses examine not only how places, peoples, and things are represented but also who is allowed to do the

representing and the ways in which this is done. Representational analyses have examined colonial power within governmental bodies and within official discourses, but they have also included less formalized, cultural institutions and popular discourses. Because it can be argued that all representations require a degree of essentialism and are therefore inherently flawed, the question of the possibility of equitable representations arises. Spivak's (1988) answer to this issue was strategic essentialism, or the acknowledgment of the need for some simplified reduction in the representations of peoples and places for a particular political agenda.

Postcolonialism developed most extensively in the 1980s and 1990s, but a number of the scholars and activists who influenced those working within a postcolonial framework predated this period. Frantz Fanon's work on colonialism in Algeria and the Caribbean and the work of the Martinique author Aimé Césaire have remained important texts within the field. More recent influences have included Homi Bhabha's work on race and hybridity and Gayatri Spivak's Marxist-feminist assessment of postcolonial and subaltern studies. Although some have considered it to be separate from postcolonial studies, the field has also been influenced by the work of the Subaltern Studies Collective. This group, composed primarily of historians, has read Indian history against the grain, seeking to rethink and rewrite history from below or from the position of the silenced subaltern subject.

Key topics of consideration within postcolonial studies have included historical projects that revisit the colonial archives to highlight the ways in which the perceived separation of the cultures and institutions of the metropole and the periphery can be contested. Said's "contrapuntal reading" critically examined the Western literary canon to point out the silencing of colonial peoples and the concealment of the darker side of colonialism. Scholars working within the realm of postcolonialism have also employed a critical Marxist framework to display the unequal distribution of political and economic power and resources within the postcolonial world, in addition to the hybrid forms of colonialism, imperialism, and neocolonialism that persist throughout the world today.

Critiques of Postcolonialism

Postcolonialism and postcolonial theory have had their fair share of critiques. Some have voiced concern that postcolonial studies are overly preoccupied with "the West" at the expense of the rest of the world. For instance, it has been asked whether postcolonial theories actually reflect the desires of colonized, formerly colonized, and subaltern peoples or if they merely serve the interests of self-conscious academics located in the global North. Most postcolonial texts are written and published in English, inspiring some to argue for publication in the languages of those people whom postcolonial studies claim to represent. Critics have challenged the notion of postcolonial studies' ability to destabilize and decenter European geographic knowledges, stating that instead they merely reposition the same knowledges at the center. The call for increased appreciation of difference is viewed by some as a return to stagnant liberal multiculturalism. Additionally, postcolonial studies have tended to be dominated by Anglophonic geography and largely concerned with British imperialism. This recognition has resulted in calls to investigate imperialisms and colonialisms located elsewhere.

Postcolonial studies' origin in literary and cultural studies has also led to a critique from disciplines within the social sciences that these textual and discursive analyses lack materiality and sacrifice substance in their focus on the immaterial. Because postcolonial theory was in its origin influenced by poststructuralist and postmodern French theory, it has been argued by others that the very core of postcolonial theory contradicts its stated aims of pluralizing knowledges and power regimes. Among other critiques of postcolonialism is its perceived simplicity. Just as postcolonialism's meaning, "after colonialism," has been problematized, the creation of dichotomous categories of "colonizer" versus "colonized" has recently been critiqued for its lack of attention to multifaceted hybridities and complicated identities not only between, but also within, those categories.

Geography's Postcolonial Subfields

Postcolonial theory within the discipline of geography has gained wide purchase. Although

postcolonialism has obviously been popular across academia, Said's discussion of the development of "imaginative geographies" piqued geographers' interest. Postcolonial geographers have investigated the spatiality of colonialism, empire, and postcolonialism from a number of different vantage points. One of the greatest impacts of postcolonialism on geography has been the acknowledgment of geographers' involvement in the colonial project. This recognition that geography has been complicit in imperial projects historically (and, some would add, today) has led to calls to decolonize the discipline. Proponents have called for the incorporation of voices outside the metropole as well as a move away from the Eurocentric geographies frequently cited in colonial contexts. Historical geographers interested in disciplinary history have been particularly interested in the creation of imperial maps, the exoticization of colonized places, the imaginative geographies constructed about those places, and the racist and determinist treatment of peoples there. Cartographers have worked to critique and rethink the normalized Western map and the collection, representation, and dissemination of various knowledges of spaces and places.

Feminist and critical historical geographies have attempted to account for the inconsistencies and silences present even within the colonial powers, noting the lack of inclusion of other voices save that of white males as well as the nonstandard historical accounts, such as travel diaries. Feminist scholars have also criticized what they consider premature self-congratulation regarding the inclusion of alternative voices. By critiquing postcolonialism from within, postcolonial feminists have sought to occupy a paradoxical position both within and without the genre. Postcolonial feminist geographies have also been particularly attentive to methodological considerations, including self-reflexivity and the negotiation of power dynamics in research praxis.

The latter part of the 20th century saw a heightened interest in identity politics throughout many academic disciplines. Geographers working within a postcolonial framework took up identity and heritage to understand how postcolonial peoples, from both the metropole and the periphery, view themselves. The celebration and reclamation

of heritage has also been a focus for geographers attending to the specificity of place and group identities. Others within geography have studied transnational migrations and the diasporas that have frequently followed and, in some cases, helped perpetuate postcolonial linkages between former colonial powers and their colonial states. These linkages have also been the central focus of postcolonial critiques of tourism and other cultural entities, such as sport. Tourism geographers have stressed the economic and cultural influences and dependencies that continue today and the continuation of colonial practices of leisure by Western travelers.

Critical development geographers have also recently employed postcolonial theory in their critiques of uneven distributions of wealth, political and cultural power, and resources. Work in this field, as well as investigations of political economy, has ranged from a challenging of the preferred nomenclature over time—from Third World/First World and periphery/core to less developed/more developed and, most recently, global South/global North, to critiques of the overwhelming domination of the World Bank and the International Monetary Fund by the Western, former colonial powers. Like the work done in postcolonial literary studies, critical development geographies have sought to challenge Western ideas of "progress" and "modernity." Actions such as the forced privatization of social services in the global South in the name of modernity have been used to expose the neo-colonialism being perpetuated by Western states and multinational companies. Reactions to the policies of Western development organizations have included both non-Westerners and radical-activist Westerners. These anticolonial acts of solidarity have become another example of anticolonial struggles in a world engaged with many forms of postcolonialism.

POSTINDUSTRIAL SOCIETY

Postindustrial society represents a major conceptual underpinning of geography and geographical discourses, with particular salience for social, economic, and urban geography as well as for allied disciplines and fields. Initially framed by the American sociologist Daniel Bell as a forecast of social change and as an explanation of social tendencies among advanced societies and states during the wrenching experiences of industrial restructuring in the latter half of the 20th century, the idea of the postindustrial society was also positioned as a critique of Marxist theories of production, labor, and social class formation and, more specifically, Marx's insistence on a

dominant social binary of capital and proletarian classes.

Initial references to the idea of the postindustrial society include David Riesman's (1958) interpretation of the term to connote leisure rather than work and an earlier invocation of postindustrial society as a hoped-for return to artisanal workshop vocations by the British Guild Socialist Arthur Pentty (*Old Worlds for New: A Study of the Post-Industrial State*) in 1917. The definitive usage was established by Daniel Bell in his seminal work *The Coming of Post-Industrial Society* (1973). Before committing to postindustrialism as a descriptor of change, Bell had experimented with the idea of alternatives such as the "knowledge society," the "information society," and the "professional society," and he also gave consideration to Dahrendorff's thesis of a post-capitalist society in *Class and Class Conflict in an Industrial Society* (1959). Bell's (1973) preference for postindustrial society as a descriptor of social transformation was derived from his sense that

we are in the midst of a vast historical change in which old social relations (which were property bound), existing power structures (centered on narrow elites), and bourgeois culture (based on notions of restraint and delayed gratification) are being rapidly eroded. (p. 37)

The sources of this historic "upheaval" are acknowledged as scientific and technological but "are also cultural, since culture, I believe, has achieved autonomy in western society" (p. 37).

According to Bell's formulation, the five dimensions or components of postindustrial society are the following:

1. **Economic sector:** The change from a goods-producing to a service economy
2. **Occupational distribution:** The preeminence of the professional and technical class
3. **Axial principle:** The centrality of theoretical knowledge as the source of information and of policy formulation for the society
4. **Future orientation:** The control of technology and technological assessment
5. **Decision making:** The creation of a new "intellectual" technology

Bell (1973) acknowledged a debt to Colin Clark, who postulated that income growth would lead to the expansion of services, and asserts that the “simplest characteristic of a post-industrial society is that the majority of the labor force is no longer engaged in agriculture or manufacturing but in services” (p. 15). Bell made a crucial distinction between the menial, low-value service employment that characterized developing societies such as India and the specialized, knowledge-intensive services that increasingly define advanced societies. These include occupations in health, education, research, and government and provided the basis for a “new intelligentsia” and, in turn, the “pre-eminence of the professional and technical class” (p. 15).

Bell’s prediction of a secular decline in industrial production and the laboring classes, and the ideological shift implied in this transition, achieved a powerful resonance within the academic and policy communities as well as fierce contestation. Criticisms of postindustrialism included opposition to the notion of an expansionist, autonomous service sector decoupled from manufacturing and industry. More specifically, scholars affirmed that the fastest-growing, most knowledge-intensive, and most deeply professionalized service industries were those most intimately linked to production: the so-called producer services. Other scholars, notably those associated with variants of Marxism, objected strenuously to the ideological tenor and policy implications of a postindustrial agenda, which implied a discounting of the value of industrial labor, class, and communities and a corresponding privileging of the interests of capital, epitomized by the neoliberal state regimes of Margaret Thatcher and Ronald Reagan.

Over the past three decades, the original emphasis on the nation-state as the unit of analysis for the study of postindustrial society has been adapted by social, urban, and economic geographers to apply principally to the urban-regional scale and, indeed, to measures of social change at the district, community, and neighborhood scales. The rise of the services class, and more particularly the managers and professionals who occupied the higher echelons of the postindustrial economy, implied far-reaching changes in advanced cities, as Bell predicted (and to some

extent deplored), expressed in political values, social attitudes, housing choices (locations, styles, forms of tenure), lifestyles, and behaviors. An early marker of class change in the city was the infiltration of professionals and managers into the old residential neighborhoods of the inner city, producing an insistent social upgrading and displacement trajectory. This process generated in turn both a policy crisis and an important new urban discourse of gentrification, pioneered by Ruth Glass in her study of occupancy change in London. By the 1990s, the process of manufacturing collapse had essentially run its course in many cities, with the postindustrial city now characterized by a dominant “new middle class” of elite service workers, including highly paid banking and financial workers, producer service professionals, entrepreneurs, and knowledge economy workers, fulfilling in large part Bell’s prophecy. At the local scale, this new middle class evinced a preference for a more “livable” and “convivial” city than that represented by the industrial city, with its manifest conditions of exploitation, materialism, segregation, and alienation. But in practice, this postindustrial, sociopolitical constituency enabled the state-supported dislocation of manufacturing and allied workers in urban districts, intensifying professionalization tendencies and pressures for social polarization.

More recently, the rise of the putative “creative class” postulated by Richard Florida and his followers presaged a new chapter in the evolution of postindustrial society. This creative class represented the social correlate of the cultural economy and workforce, seen as following “neo-Bohemian” housing and lifestyle patterns distinct in some respects from those of the new middle class, much as the behaviors of the latter constituted a departure from those of the industrial classes. But others contest this proposition of a quasi-autonomous creative class, instead asserting that cultural workers were always encompassed within the parameters of the new middle class and indeed were acknowledged as constitutive elements of Bell’s postindustrial society. This contemporary debate underscores the continuing relevance of Bell’s postindustrial theory for urban studies.

POSTMODERNISM

The term *postmodernism* appeared in academic geography in the late 1980s, although it had been circulating earlier in several disciplines and professions. The term is often used in two different ways. First, it designates an object of study whereby researchers examine some feature that is seen to be postmodern in style, character, or design. Commonly identified postmodern objects include buildings, cities, cultures, societies, and economies, although this last object is often described using the related term *post-Fordist*. The clustering of such postmodern objects together may be seen to imply that people are, in at least some places in the world, living in a distinctive epoch or condition of postmodernity. The other way that the term *postmodernism* is often used is to imply an approach (or as it has also been described, attitude, method, or sensibility) to viewing and understanding the world and how it operates.

This entry briefly outlines how these two views of postmodernism arose and considers how they interconnect in the work of two geographers, David Harvey and Michael Dear. The entry also examines the impact of postmodernism, identifying three contrasting interpretations.

Postmodernism as Object

One of the fields where postmodernism emerged initially was in architecture, where the term

was used as an identifier of a new style that was different from and, indeed, critical of modernist design, which had risen to prominence in the 20th century but whose focus on the adoption of functionality, efficiency, and separation from the past had by the 1960s become subject to widespread criticism. It was at this time that architects such as Peter Eisenman, Frank Gehry, Peter Johnston, and Robert Venturi began to create new architectural designs that were promoted as being more in tune with and, indeed, learning from the performance of everyday human life. The rectilinearity and standardization characteristic of modernist architecture were replaced by an emphasis on diverse surfaces, textures, and forms, which often combined elements from both contemporary popular culture and a range of prior architectural styles.

The ideas circulating within architecture began to infuse academic studies of urban design and social life, notably through the work of Christopher Jenks and Frederick Jameson, and in the late 1980s, geographers began to make reference to the term *postmodernism*. In many of these studies, the term was not only applied to the design of particular buildings but also used to characterize whole cities. Edward Soja, for instance, presented Los Angeles as the quintessential postmodern city because it was composed of a plethora of urban forms reflective of a series of different divisions and fractures that came together to produce a collage of fragmentary images and experiences. David Harvey made a similar argument, albeit generalizing it to a range of North American cities that he suggested exhibited postmodernity through numerous cultural signs and images that constituted a sort of messy social collage, or pastiche, of meanings within which there was no apparent order. Postmodern architects, artists, filmmakers, and other cultural image makers were, in effect, codifying and representing a condition of social life that was already being experienced by many urban inhabitants.

Harvey's work, while clearly centered on cities, clearly illustrates how postmodernism could be identified in all manner of objects. At least two features tie these postmodern objects together. First, they are seen in some sense or other as new objects that can be contrasted with

something that went before and that was designated as modern. The “post” prefix in part therefore encompassed notions of temporal change, with postmodernism being viewed, in part, as a periodizing concept, although this usage was contested by a series of authors who argued that the term should not necessarily imply a clean break with modernism but could also be viewed as a continuation, albeit in a slightly new form.

A second aspect of postmodern objects is that they are seen to be highly complex and fluid, in contrast to what went before, which was seen to be regular and largely static in form. In relationship to buildings and urban form, postmodernism was seen to involve a movement from redevelopment focused on the construction of large rectilinear buildings and street layouts with clear and static divisions of land use, often bearing no relation to earlier forms of development, to regeneration whereby existing buildings were often modernized rather than replaced and new buildings were slotted into the fabric of existing buildings, both physically and symbolically, with many drawing on local building styles that were combined, sometimes quite ironically, with other, more modernistic and globalized elements. The result was a complex mix or pastiche of architectural styles and land use, often within a complex, multilayered street plan that involved multiple and changeable use of space.

Complexity and fluidity are also evident within other postmodern objects. Attention has been drawn, for instance, to the multiplicity, changeability, and hybridity of identities in contemporary pop music; leisure, recreation, and tourism; films and television programs; and the marketing and purchase of consumer commodities. Some scholars have also drawn attention to organizational changes in economic production whereby so-called post-Fordist economies have seen the rise of flexible and just-in-time production, often oriented to the production of niche and fashion products, and how these are connected to the cultural changes associated with postmodernism. Most prominent in this respect was David Harvey's book *The Condition of Postmodernity*, published in 1989, which argued that postmodernity was the product of a shift in capitalism toward flexible accumulation.

Postmodernism as Attitude

An emphasis on complexity and fluidity is also characteristic of “postmodernism as attitude,” although these descriptors are here applied to the conduct of finding out about the world as well as to the character of that world, or to put it more formally, postmodernism involved radically different epistemologies and ontologies from those previously enacted within geography.

Postmodern Ontologies

Connecting ideas of complexity and fluidity identified in various postmodern objects to the research process, postmodernism as attitude stressed at least two lines of ontological arguments. First, it was argued that modernist approaches tend to draw on “metanarratives” or “grand theories.” Metanarratives can be seen as “big stories” that serve to organize phenomena or events into some seemingly meaningful temporal order or pattern, centered around some central principle or plot, such as the growth of knowledge/reduction of ignorance or false belief, the realization of the human spirit, increasing control of nature, or emancipation from social control. All these narratives have been influential in geography at points in the recent past: the first of these, for example, underpinning positivist approaches to geography; the second, many strands of humanistic geography; and the third and fourth forming elements of Marxist approaches as well as a range of more liberal perspectives.

Many metanarratives involve grand theories, which are claims to understand how the world operates through the identification of concepts viewed as corresponding or referring to some central mechanisms or processes considered as propelling phenomena and events within much of the world. So, for instance, many positivist approaches drew on concepts such as economic rationality and profit maximization, humanistic geographies on notions such as authenticity and belonging, and Marxism on concepts such as modes of production and class struggle. While identifying quite different key concepts, and therefore often being seen as quite incompatible with each other, these approaches arguably all

shared a similar ontological stance in that the world is seen to be conditioned or ordered according to some central logic.

Postmodernism as attitude expresses, minimally, skepticism about the value of metanarratives and grand concepts and often complete rejection, as in Michael Dear's (2000) claim that the ideal of postmodernism is for a philosophical culture "free from the search for ultimate foundations of everything" (p. 35). Such a view, often characterized as a relativist position in which there are no singular, absolute truths but rather a range of different and equally valid perspectives, attracted considerable criticism, particularly in the late 1980s and early 1990s, when even some of the advocates of postmodernism expressed concern. However, it is clear that strands of postmodernist arguments have come to be widely accepted within geography, even among those who would not explicitly consider themselves to be postmodernist. From the late 1980s, for instance, there has been a growing recognition of the disorderly and contingent within geographical studies and how many aspects of the social and physical worlds do not seem to fit within some overarching logic or structure. There has been increasing resistance to the notion of developing general and hierarchical ontologies, whereby some features or processes are seen to be more significant, more foundational than others. In contrast, postmodernism can be seen to imply nonhierarchical and localized ontologies, whereby events, phenomena, and processes emerge because of the particular relationships that come to exist between all manner of elements that are copresent within particular times and spaces. Such a viewpoint creates a new, more humble role for theory, as explanations cannot be specified in advance of a particular study or transferred directly from one context to another. It also creates a stronger role for description than had been the case in many earlier, modernist perspectives, with attention being drawn, for instance, to notions of thick description and local knowledges as advanced by the anthropologist Clifford Geertz, as well as increasing attention being paid to the value of qualitative research methods, which arguably can be seen as part and parcel of a postmodernist approach to geography, just as quantitative methods had become widely equated with positivist philosophies.

A second ontological concern of postmodernism closely associated with its concern to avoid grand theory is a concern with difference. In part, this involved questioning of the assumption made within many modernist perspectives that explanation relied on seeking out the similarities between events, objects, or processes and suggesting that such approaches often resulted in crucial aspects of situations being overlooked. Moreover, it involved questioning of the categories of difference that entered into the accounts being created, suggesting that these were often far more diverse, complicated, and fluid than was often presupposed in modernist theories. Chris Philo, in a discussion of postmodernism in rural geography, for example, suggested that people had largely been portrayed as essentially similar to each other, and to those who were studying them, in that there was an implicit focus on people who were white, male, middle class, middle-aged, able-bodied, sound minded, and heterosexual. He suggested that this focus on "the same" needed to be supplemented by a study of "neglected others," people who were, in one way or another, different from the societal norm.

The study of "others" formed a focus for much geographical work in human geography from the late 1980s, with Michael Dear, one of the earliest proponents of postmodernism in geography, arguing in his book *The Postmodern Urban Condition* that postmodernism has had a liberating effect on previously marginalized voices, including women, people with disabilities, gays and lesbians, people of color, and the economically and socially disadvantaged. There has been an enlarging portfolio of people studied by human geographers, although concern has been expressed about practicalities, the ethics and politics of studies of "the other," and the possibility that postmodern ontologies and epistemologies are not fully compatible with the projects of other perspectives that have sought to give voice to neglected groups and interests, such as feminism, postcolonialism, and queer theory. Attention has also been drawn to "differences within the same," that is, how people who might be seen in many respects to fit into a societal group may in some respects be quite different from others in that group. Hence, for instance, one impact of postmodernism has been to foster attention on the

differences between women, a focus that has been described as characteristic of postmodern feminism and/or postfeminism.

Postmodern Epistemology

In relation to epistemology, postmodernism can be considered as involving a rejection of, or at least a movement away from, modern views on knowledge. At least since the European Renaissance, and probably well before, the acquisition of knowledge has been widely seen as emancipatory, holding, at least potentially, prospects of freedom from social and natural constraints. This viewpoint was quite explicitly articulated in the European Enlightenment of the 17th and 18th centuries and can be seen to infuse the metanarratives that have informed many of the philosophical perspectives that have, as noted earlier, been processed through geography through the course of the 20th century. However, a key strand of the postmodern critique of grand narratives has been to question, and in some cases completely reject, Enlightenment perspectives, not only highlighting that acquisition of knowledge frequently does not seem to lead to emancipation from necessity and social control but also, in the work of people such as Jean-François Lyotard, Michael Foucault, and Jacques Derrida, suggesting that knowledge and writing are themselves forms of power, containing strategies of both exclusion and suppression.

Three ideas have often been foregrounded in the postmodern critique of Enlightenment notions of knowledge and truth. First, and closely connected to the critique of grand theory discussed previously, there have been calls to recognize the limits and partial character of theory. Many arguments here focus on the issue of representation, with skepticism being expressed both about the ability of theoretical concepts to “cognitively map” the complexity and fluidity of the postmodern world and, more fundamentally, about whether concepts could ever be seen to correspond, in a meaningful way, to the phenomena they purportedly represent. There is a clear line of connection between the latter argument and poststructuralist criticisms of representational theories of truth. While modernist epistemologies

often draw implicitly on mimetic or correspondence theories of truth, whereby the truth or falsity of concepts is seen to reflect the degree to which they accurately align with/reflect the phenomena to which they refer, a range of writers associated with poststructuralism, including Baudrillard and Derrida, have questioned whether concepts have any linkage to anything beyond other concepts or signs.

As well as stressing the problems of representation, postmodern discussions of epistemology have also highlighted the situatedness of knowledge: how knowledge is always constructed from a position somewhere within society. This view is contrasted with the objectivist position of many modernist epistemologies that situated the researcher as ideally being some disembodied viewer surveying a world from which he or she had become detached. Not only was this positioning criticized as being impossible to realize, but in the 1990s, a series of other, explicitly situated positionings came to be advanced, including calls to view things “from below,” “from the margins,” “from the inside-out,” “from the streets,” “from the borders or contact zones,” and “from the in-between,” as well as through “traveling” and “nomadism.” As well as these calls for particular spatialized epistemologies, there were also more general calls for geographers to create more contextualized epistemologies by reflecting on and making reference to their own situatedness and positionality and how who one is determines what knowledge one generates.

A third epistemological aspect of postmodernism, closely connected to issues of positionality and situatedness, is the particularization of critique. While many postmodern geographers still retain an allegiance to some notion of critical geography committed to considering not only “what is” but also “what could be,” many are skeptical about the quite general, collective, transcendence of the present espoused by earlier radical, Marxist, and feminist geographers. Postmodernists have instead tended to focus on more partial and personally situated critiques centered on the interests, experiences, and problems of particular social groups. As a consequence, postmodernism has both drawn on and fostered perspectives such as postcolonialism, queer theory, and some strands of feminism.

Postmodern Objects and Modern/Postmodern Approaches

The consideration of postmodernism as both object and approach provides the possibility that the former can be approached both in a postmodern way and in a way that might be described as modernist, a possibility that has been clearly realized in the studies of the postmodern city by David Harvey and Michael Dear. As previously noted, the former's book *The Condition of Postmodernity* was one of the first geographical studies identifying cities as postmodern objects. Harvey, however, adopted a modernist approach in arguing that the conditions of living in postmodernity were themselves conditioned, or created, by processes that could be identified through Marxist conceptions of capitalism. This argument developed earlier work by Jameson that claimed that postmodernism represented the "cultural logic" of late capitalism.

Such viewpoints have, however, been strongly criticized, not the least by those who draw on ideas from postmodernism as approach. Michael Dear, in *The Postmodern Urban Condition*, for example, argues that Harvey fails to engage sufficiently with the issues of difference, epistemology, and politics highlighted by postmodernism as approach. Dear, in contrast, seeks to embrace the challenges posed by postmodernism as approach, constructing a series of explicitly personal and partial accounts of selected aspects of postmodern cities, particularly Los Angeles, which are not seen to necessarily make sense when taken together and among which none is seen as more explanatory than any of the others. Dear explicitly argues that he expects his embrace of a postmodern approach to urban postmodernity to be received skeptically by many, but his work bears similarities to notions of new urbanism advanced by people such as Ash Amin and Nigel Thrift. New urbanism shares an emphasis with postmodernism on the complexity and fluidity of urban life and on the limited power of theory, although here inspiration comes primarily from the work of people often associated with poststructuralism and actor-network theory.

Impacts of Postmodernism

The impacts of postmodernism on geography, and indeed most other disciplines in the social sciences and humanities, have been both considerable and highly contested, although people coming upon them now may find it difficult to appreciate their significance in that there is perhaps a feeling that, to use a periodizing concept of "post," human geography and many other disciplines and professions may be in a post-postmodern era or condition. David Ley, for instance, has suggested that usage of the term in the social sciences peaked in 1992 and a decade later had entered a phase of "unlamented decline." He adds that postmodernism's relatively short period of prominence could be interpreted in a range of different ways. It could, for one, be seen as reflective of a problematic concept, with postmodernists failing to transcend the limitations that they had identified in modernism. Alternatively, it could be argued that its impact was limited to the creation of a form of intellectual capital that, although significant in terms of building the career of a generation of human geographers in the 1990s, became subsequently devalued as its distinctiveness declined. A third interpretation is that the lack of explicit reference to postmodernism today is actually reflective of success, with postmodernism becoming part of the established way of doing human geography and other social sciences. Postmodernism has in effect become less remarked on as it has become naturalized, perhaps even domesticated. Furthermore, many of its concerns have clearly come to be pursued using new or reworked labels, such as poststructuralism, postcolonialism, postfeminism, queer theory, nonrepresentation theory, and critical theory/geography. This clearly does not mean that all the issues raised by postmodernism have come to be resolved in these other approaches, and hence, the challenge of postmodernism may still very much be a continuing one for human geography.

POSTSTRUCTURALISM

Though not always easily defined or clearly separated from postmodernism, poststructuralism was a groundbreaking shift in epistemology that occurred throughout the social sciences beginning in the late 1960s. It can be generalized as a system of thought that rejects the possibility of a single knowable “truth” by acknowledging a multiplicity of meanings that are constantly in the process of being created and changed. Poststructuralism, furthermore, emphasizes the power of discourse to create reality and inscribe subjects and uses this knowledge to create politically active theory and research. This entry discusses the origins of poststructuralism and the ways in which geographers have used poststructural theory.

Origins of Poststructuralism

Poststructuralism emerged in continental philosophy in the 1960s as a response to structuralist theories. Structuralism began as a linguistic theory espoused by Ferdinand de Saussure but then morphed into theories used throughout the social sciences. Saussure’s main contribution was to argue that the relationship between any given language’s words (signifiers) and the objects or ideas they represent (signified) was not a given fact but was, instead, arbitrarily produced through the differentiation of various signs or symbols from other signs. Saussure argued that, given this fact, it was impossible to see language as merely a Platonic reflection of the “real” world. Rather, a person must make the effort to understand the structures or rules that govern the application of signs to specific objects in order to understand how any language works.

This theory of language was then reinterpreted and applied in numerous other fields, but of particular importance to geography was its application in anthropology. Claude Lévi-Strauss applied Saussure’s theories to the study of culture in an effort to move away from teleological explanations of cultural evolution. Lévi-Strauss argued that the specific cultural traits of any society, such as rules regarding succession or kinship, were simply surface phenomena that reflected the deeper, structural rules shared by all societies. If

an anthropologist could look below the surface cultural phenomena, Lévi-Strauss argued, he or she could find the base structures that governed *all* cultures. The classic example for Lévi-Strauss would be the incest taboo, which he argued formed the basis for mating and procreation rules for all societies.

Other structuralist thinkers emphasized different bases for their analyses, but the basic explanatory rules remained the same; surface phenomena could be explained only through an analysis of the base mechanisms that controlled them. Structural Marxists such as Louis Althusser, for example, argued that in capitalist societies, all activity is predicated on and dictated by the economy. While other motivations may appear to hold sway, in the end, it is the economic that will determine surface activity.

Poststructural analysis began in earnest with the French philosophers Roland Barthes and Jacques Derrida in the mid 1960s. It was during this time that Barthes began to talk of the “death of the author,” arguing that the meaning of texts lay not with the author or with some sort of underlying structural rules but rather with the reader, who brought his or her own experiences and interpretations to any work. Meaning was not inherent in any work, but was subjective, something that was created by the interaction of the reader and the text, a text and society (context), or a text and other texts (intertext). Meaning under these terms became relational—that is, made and not given—not something that simply existed but rather something that came into being through interaction or mutual construction. This line of thought had important significance, not just for literary analysis but also for social science in general. Because meaning is not a given, there is no single “truth” that exists separate from social context and simply awaits “discovery.” There are instead multitudes of meanings and truths, and these meanings are all historically and (perhaps most important to geographers) spatially specific. Where structuralists saw systems and meanings that were closed and rigidly defined, poststructuralists see systems of meaning that are multiple, constantly evolving, and re-created through interactions with other systems.

Jacques Derrida questioned the very logic of identity and meaning in modern society. Through

the use of his methodology of deconstruction, Derrida exposed the flaws in the modernist project of constructing meanings through binary oppositions, which he called logocentrism. Derrida argued that these binary constructions included inherent value judgments that rendered the negative side of the binary, for example, the “not male” side of the male/female binary, as inherently less valuable. The goal of deconstruction is to expose the flaws in the logic behind these binaries, to force an acknowledgement of multiple possibilities. Feminist geographers have proven particularly effective in using this critique to show the masculinist tendencies in much geographical analysis. Female economic geographers, for example, have used deconstruction to show the way in which traditional definitions of economic activity have elided the productive economic work done by women. In doing so, they have exposed new spaces of economic activity, formerly defined as sites of reproduction rather than production, and opened them up to analysis.

Geography and Poststructuralism

Geographers have taken to poststructural theory in a number of important ways, particularly in economic geography, whose fields it has helped reinvigorate, and in the field of cultural geography, which it rescued from academic irrelevance. Poststructural theory opened new objects for analysis, for nearly anything could be read as text and all meanings were inherently multiple and contested. The acknowledgement of multiple meanings has been particularly fruitful for geographers, as they have sought to give voice to groups that have been marginalized in earlier forms of analysis, relocating the importance of discourses from the center to the margins. Furthermore, in acknowledging that the views and meanings of certain groups have been privileged in the past, poststructural geographies have become adept at analyzing the creation of both power and resistance.

Finally, poststructural theory has allowed the idea of space itself to be dramatically reconfigured. The realization that the meaning of texts is not inherent but subjective and that any object can be read as a text has opened up all sorts of

subjects to new geographical analyses. In this regard, the study of landscapes has been particularly invigorated by the adoption of poststructural techniques. Under the Berkeley School, landscapes were read as artifacts of culture, but their role in cultural production was not considered or even acknowledged. Poststructuralist geographers now look at the role that landscapes play in re-creating culture. Landscapes represent cultural discourses made concrete. They reflect the values and power relations that brought them into being. Furthermore, these manifestations of discourse are part of everyday occupied space. As such, they perform cultural work on all those who occupy them, either reaffirming the values that created them or encouraging acts of resistance.

Michel Foucault, the famed French philosopher, offered much to the development of a poststructural geography. A primary interest for Foucault was the connection between knowledge and power and the ways in which discourses of knowledge could be used to proscribe and discipline others. Foucault exposed the connections between discourse, knowledge, and power through the twin methodologies of archaeology and genealogy. In his early works of archaeology, such as *Madness and Civilization*, Foucault emphasized how discourses (broadly accepted facts and expertise, along with their accompanying institutions and social practices) limited what was conceivable at any given moment. By tracing the changing definition of insanity, Foucault showed how institutions created discourses that defined terms such as *madness* and, in doing so, created subjects who were then labeled as mad. By showing the historical specificity and politicized nature of various discourses, Foucault challenged notions of permanence or singular truth. Foucault also noted that the creation of new discourses often required the creation of new spaces for the enactment of those discourses (asylums, prisons, institutions, etc.). In this phase, Foucault showed that discourses, far from being consistent and independent, are historically situated and specific and are frequently co-constitutive of spaces.

In his genealogy phase, Foucault became increasingly interested in the power enacted around discourses. Here, he explored how discourse becomes

practices manifested in subjects. Thus, the body becomes the site where discourse is made manifest. Foucault's studies created a sort of geography of power. The ability of a discourse to be enforced on a body is a clear display of power. Sometimes, as in the case of Bentham's panopticon, in which prisoners are observed by an unseen, presumably all-seeing guard, who watches from on high in a central tower, power is centralized. But more often, Foucault was interested in the ways power from discourse acts in a decentralized manner. Because discourse is given the status of fact, subjects regulate themselves to conform to it. He argued that to truly understand the workings of power, one mustn't start at the center and analyze outward, but instead, one must start at the fringes and work inward. One needs to understand how power works on the micro- or local level rather than from top down. Furthermore, power is not always wielded by one group against another but is in constant flux and circulation.

Foucault's methods of analysis and exploration of discourse have been taken up by a number of geographers exploring the traditionally marginalized groups in Western thought. Edward Said's classic text, *Orientalism*, used Foucauldian analysis to explore how Europe defined itself by applying discourses of "otherness" on Asia. Other geographers have taken up genealogy to show how groups outside the global North are often constructed by its discourses. The anthropologist Arturo Escobar traced the discursive creation of the "Third World" to show how development has operated as a discourse that pathologizes the social and economic practices of countries that are deemed to be "developing." More recently, economic geographers have begun to analyze the genealogy of the discourse of globalization in an attempt to shatter the illusion of that process's inevitability. Geographers of gender have also used Foucauldian analyses to explore the pathologization and subsequent spatialization of gender and sexuality on the landscape.

The philosophizing of space has also been invigorated by poststructuralist thought. Previously a taken-for-granted entity, under poststructuralism, all space is relational. It is not an empty, value-less plane on which activities occur; rather,

it is created by the actions of the actors within it. Space, therefore, can have multiple meanings and uses, and because it is made through the interaction of actors, space is never closed or cut off but is always in the process of being made, of becoming. To the extent that one spatial formation can become dominant at a given moment, space is also the site of both power formation and acts of contestation and resistance.

Bruno Latour, a French sociologist, conceived of space as created by a series of networks connected through linkages. The operation of these networks helps better explain how Foucault's ideas of power at the micro- or local level (e.g., in an asylum or within an institution) can be extended to unconfined space. Nodes in the network are added through the processes of recruitment and translation. A central actor recruits nodes that consent to become a part of the network because they share its goals in some way. But in enrolling in the network, they are translated by it, inexorably changed to meet the demands of the network. This translation is a form of discipline. Networks gain strength by their number of connections. Thus, a network is composed of actors, but it is also an actor itself, working to achieve some goal. This combination of roles as both actor and network gives name to this particular mode of analysis—actor-network theory.

To Latour and other actor-network theorists, space does not exist outside a network; it is created through the actions of networks in bringing people and materials together. Networks create space, and that space exists at all scales. Individual actors perform functions at the local level, but networks extend as far as they have connections; therefore, they are capable of being at once both global and local. Geographical analysis, then, means following a network wherever it may lead. This means the investigator can assume no preexisting hierarchical structure but must simply follow the connections between nodes. This type of analysis once again problematizes the idea of a central concentration of power. Power in the network is diffused, spread between nodes, flowing inward and outward, as the actors at each node have their own agency. Further complicating this web of interaction is the fact that multiple networks can and do exist simultaneously. This means that individual places have

multiple meanings at any given moment. Society under this mode of analysis is simply a collection of multiple overlapping networks.

Theorists such as Gilles Deleuze and John Law prefer to think of space as even more complicated than the multiple spaces of actor-network theory. They argue that space is fluid, never fixed, but forever in the act of becoming. Since space is an area of contested meaning, with multiple actors or networks competing to define it, it is never stable or singular; it is always in the process of becoming something else. In this sense, space is unknowable. To these theorists, space is not a plane but is rippled, folded, and ruptured. Objects that are distant in a Euclidean sense can be seen as folded close together in topological space due to their connectivity via networks, while objects in close proximity may exist on entirely different planes, in different spaces. This theorizing of fluid space attempts to take into account groups or individuals who may not be incorporated in any network.

While poststructuralism and its intellectual cousin, postmodernism, have been criticized for being “anything goes” types of theory, this is far from the case. Poststructuralist analysis is a political act, designed to decenter ideas that have been accepted as fact in order to open readers and investigators to new possibilities of futures and presents previously unimaginable under modernist logical conventions.

POVERTY

Poverty is deprivation of material essentials such as food, shelter, drinking water, and clothing. It is also associated with the lack of education, freedom, and dignity. The uneven distribution of poverty at various scales, from the global to the household, via the national, regional, and local, suggests the importance of geographic factors in explaining its prevalence and understanding its nature.

Poverty Measures

There is disagreement on how best to measure poverty. The first distinction exists between absolute and relative measures. Absolute measures identify a minimum level of income or consumption below which individuals or households are considered poor. For example, the World Bank defines extreme poverty as less than \$1 per day and moderate poverty as less than \$2 per day, with purchasing power parity adjustments allowing comparisons between countries. Because standards of living vary dramatically across places, most countries have established their own absolute poverty lines. In the United States, the poverty threshold was established in 1965 based on the cost of food, taking into account household size and composition but making no adjustment for regional differences in cost of living. The threshold is adjusted annually for inflation. For example, in 2007, the federal poverty threshold for a family of three, with one adult and two children, was \$16,705—far above the extreme world poverty measure but well below the national average income.

Income-based measures have led to some criticism that monetary amounts do not directly translate into human well-being. The Nobel laureate Amartya Sen argues that poverty is the deprivation of basic capabilities to lead the kind of life one chooses. Although income is instrumental in reaching this goal, its impact is conditional and varies between different communities, families, and even individuals. To address these shortcomings, in 1997, the United Nations constructed the Human Poverty Index (HPI) based on three components: life expectancy, education, and economic provisioning. Although correlated with per capita

income, the HPI does not yield the same ranking of countries as the World Bank's extreme poverty measures, suggesting that social structures, government policies, and other local attributes can influence the quality of life.

Relative poverty measures conceptualize poverty as socially constructed and dependent on the social context. Within this perspective, the poverty threshold is defined in relation to a national or regional benchmark rather than in absolute terms. One of the most common measures sets the poverty cutoff at a given percentage—usually 50% or 60%—of the national or regional median income. Another approach defines poor people as those in the bottom percentiles of the income distribution. Thus, relative poverty and inequality are connected to the extent that the former results from a sense of deprivation emanating from a substandard economic position. Relative poverty measures are used more extensively in developed nations, where extreme poverty is less prevalent but people with incomes significantly lower than the median experience economic deprivation, social exclusion, and limited ability to participate in society.

The Distribution of Poverty

Poverty varies both demographically and geographically. In 2004, there were close to 1 billion people in the world living on less than \$1 per day, a decrease of 250 million since 1990 and a step toward reaching the United Nations' Millennium Development Goal of reducing extreme poverty by half by 2015. Poverty, however, is not distributed evenly (Figure 1). Most of its recent decline can be attributed to East Asian countries. Although the majority of poor people remain in South Asia, poverty has increased most rapidly in sub-Saharan Africa, where almost 300 million people, or 41% of the population, live on less than \$1 per day. Poverty recently increased in Western Asia and remains fairly constant in Latin America. Many Latin American countries such as Ecuador, Argentina, and Nicaragua fare better on the HPI than on income poverty. This contrasts with African countries such as Morocco, Egypt, Algeria, Senegal, and Burkina Faso, where the HPI rankings are worse than expected, given the poverty rates.

Some of the gains in absolute poverty are overshadowed by increases in inequality and

Figure 1 Percentage of population living on less than \$1 per day

Source: Data from United Nations Development Programme. (2007). *Human development report 2007/2008*. New York: Palgrave Macmillan.

worsening relative poverty in most of the developing world, where the poorest quintile accounts for less than 4% of national consumption. Inequality is particularly acute in Latin America, the Caribbean, and sub-Saharan Africa.

Although extreme poverty is virtually nonexistent in the Organization for Economic Cooperation and Development (OECD) countries, national measures indicate the presence of economic deprivation. For example, in the United States in 2006, 38.8 million people, or 13.3% of the population, fell below the federal poverty line.

Of course, important variations exist within regions and nations. Although poverty rates are usually higher in rural areas, a large and growing number of poor people live in urbanized areas, with a significant degree of concentration and clustering in specific neighborhoods and informal settlements. Throughout the world, racial, ethnic, and religious minorities; indigenous populations; and women and children are more likely to suffer from poverty.

Causes of Poverty

Multiple factors operating at various interconnected scales cause poverty. Globally, uneven trade and capital flows lead to poverty through exclusion from the benefits of economic growth. Access to water and natural resources, transportation, and climate also shape physical abilities and economic opportunities. International and national policies influence poverty directly, through aid, subsidies, and antipoverty programs, and indirectly, through economic policies that affect the allocation of resources between people, regions, and industries. While some argue that individual characteristics such as education and the work ethic are paramount in explaining poverty, others insist that social and economic structures define capabilities based on gender, class, caste, race, religion, and other forces. Women are often denied access to education, paid employment, health care, financial resources, and political participation because of their gender. While

these socially embedded practices deprive women of economic opportunities and basic freedoms, they also contribute to poverty indirectly through fertility and child care.

In the United States, the rise of “working poverty” has been linked to economic restructuring and the decline of the welfare state. The role of these factors varies from place to place and underscores the importance of geography in understanding poverty.

POWELL, JOHN WESLEY (1834–1902)

John Wesley Powell, an American explorer, scientific frontiersman, teacher, military leader, geologist, naturalist, government administrator, ethnographer, and geographer, is best known for having been the first to explore the length of the Colorado River through the Grand Canyon. According to William Morris Davis, Powell laid the

foundation for American geomorphology and profoundly influenced those who came after him.

Born in Mount Morris, New York, Powell spent many of his early years in Ohio, Wisconsin, and Illinois. His father, a dedicated Methodist abolitionist preacher and farmer, moved the family frequently to serve various congregations. John had obligations on the farm owing to his father's frequent absences. Irregularly educated, he received considerable natural history training from a neighbor, who provided a classroom, a small library, a laboratory, and field instruction.

By age 18, he was teaching school, studying, traveling, and collecting specimens locally, and he furthered his own education by planning and executing trips on the Ohio, Des Moines, Illinois, and Mississippi rivers. Though he never graduated, he did manage to complete approximately 2 yrs. (years) of university training.

At the outbreak of the Civil War, having enlisted in the Twentieth Illinois Infantry, he was very quickly promoted to sergeant and to second lieutenant. Assignments included engineering roads and bridges and establishing camps and battlements. Struck in the lower right arm by a rifle shot at Shiloh, his lower arm was amputated; however, he remained in the army for 3 more yrs. and was later stationed at Vicksburg, where he commanded artillery. During one of his military leaves, Powell married Emma Dean from Detroit.

After the war, he took a professorship at Illinois Wesleyan University and Illinois Normal School, teaching a variety of science classes. An advocate for increased science and fieldwork in college curricula, he organized a field trip in 1867 across the Great Plains to the Rocky Mountains with his wife and students. This event led him to organize his first trip down the Colorado River in 1869.

Embarking on May 24, 1869, the expedition included four wooden boats, manufactured in Chicago and delivered by rail to Green River, Wyoming; supplies for months of travel; and 10 men from various backgrounds. They floated on the Green, through the Uinta Mountains to the junction with the Grand River and into the Grand Canyon. Vertical cliffs, giant rapids, and steep falls made progress slow and difficult. Even with near disasters, including the loss of supplies, scientific equipment, and most of the food, the party emerged from the canyon more

than 3 months after departure. During the journey, Powell documented geologic columns, identified fossils, recorded elevations with a barometer, and kept careful scientific records. He later conducted further research in the plateaus of the Colorado, focusing on geology, geomorphology, and ethnology.

Powell's contribution to geology, geomorphology, and geography are considerable. He classified landform regions of the United States, mountain types, and stream drainage systems. He developed concepts such as the graded stream, the base level of erosion, superposition, and antecedent rivers, which led later geomorphologists to unifying theories. He recognized that landforms evolve as the result of differential removal of materials; he explained surface processes and landforms and that uplift and erosion are slow processes. These concepts reinforced the notion of uniformitarianism, the doctrine that processes operate in the same way over geologic time. He carefully observed and documented landscape features, having measured stratigraphy, lithology, and fossils throughout the Grand Canyon and Colorado plateaus.

Powell possessed great vision about the future of the Western United States, particularly its water issues, cautioning in various reports that the western lands were fragile and that water would be a controlling factor in settlement. He recognized that only a small percentage of the western lands were suitable for agriculture owing to water scarcity. He also knew that water allocation in the west must be treated differently than in the Eastern U.S. model, in which water rights go with the land. Powell also encouraged further hydrologic studies to understand the behavior of water. He advocated stream discharge measurements, careful record keeping, and the identification of potential reservoir sites.

Powell enjoyed a second career as an administrator in Washington, D.C., after having developed associations with Congress and governmental officials while fund raising for expeditions. He had developed sympathy, trust, and respect for Native Americans during his explorations, and his study of Native Americans led to his appointment as ethnographer of the Smithsonian in 1879. He served as the director of the Smithsonian's Bureau of Ethnology until his death in 1902. At the Smithsonian, Powell assembled a group of

talented scholars, and significant ethnographic projects emerged. Under his authority, the Indian Linguistic Families of North America report and map were published.

Powell became the second director of the young U.S. Geological Survey (USGS) in 1881. Under his direction, the USGS budget grew. He developed an effective team of experts and produced many outstanding reports. A significant contribution to the USGS was the development of topographic maps with contour lines representing topography rather than the European hachure model. He insisted that these maps be simple, produced for the entire country, and useable by miners, cattlemen, farmers, and geologists. In 1894, he resigned from the USGS, as appropriations began to shrink due to pressure on Washington decision makers for unbridled western development. His ideas about the west and its water issues were getting in the way of developers. As a result, he stepped down from the USGS directorship.

Powell was significantly involved in the establishment and leadership of many local and national scientific societies, including the American Anthropology Association; the National Geographic Society, which, at that time, published a scholarly scientific journal; the American Association for the Advancement of Science; and the Geological Society of America.

PRAIRIE RESTORATION

Across the world, prairies are among the most manipulated landscapes as prime sites for grain crops such as wheat and corn. Found in semiarid regions such as the North American Midwest and the Russian steppe, their mix of grasses and forbs (broadleaved herbs) sends roots deep. The native plants support a rich mix of animals, insects, and birds; the substitution of monocultural grain crops harms them. Prairie restorations are attempts to recover diversity by reintroducing a wide array of native plants. Full prairie restoration includes disturbances from periodic fires, which clear surface plant matter while reinvigorating the soils, and migration by native animals, whose hooves break up the topsoil layer to make way for new fresh growth once they have passed.

Early pioneers in prairie restoration include Midwesterners such as Jens Jensen (1860–1951)

and Aldo Leopold (1887–1948). Jensen, a landscape architect, was instrumental in developing an aesthetic of native plants, seeing them as worthy rather than as weeds. Leopold's *Sand County Almanac* simply and beautifully describes the year he spent bringing back a degraded Wisconsin property. His writing celebrates unappreciated native plants such as the delphinium, which serendipitously survived, ignored along the railroad right-of-way. Leopold used his experience to develop a land ethic based on honoring the complexity of ecosystems and on an acknowledgment that health requires maintaining the interactions between species—the basis of prairie restoration. Leopold's ideas inspired many in the tallgrass prairie region, and groups in states such as Wisconsin, Iowa, Illinois, and Kansas have been leaders in prairie restoration. Academics and universities, land restoration organizations such as The Nature Conservancy, and citizen groups acquire land and develop prairie research and

Land managers set fire to a prairie burn with drip torches to stimulate new growth and recycle nutrients at Konza Biological Research Station, Manhattan, Kansas.

restoration programs. The Society for Ecological Restoration is the professional association committed to such efforts.

Restoration in the more western, drier, short-grass prairie has been a bit less active, perhaps because more of the ecosystem remains intact, though degraded particularly by the loss of animal species. Lands that have been grazed but not put to cultivation of crops still harbor native plants that revive when management mimics preagricultural patterns. Short-grass prairie restoration tends to emphasize native animals; for the American Prairie Foundation in Montana and the Grasslands National Park in Saskatchewan, for example, bison restoration is central. These efforts bring to life the concept of the *Buffalo Commons*, a term coined by Deborah and Frank Popper, advocating the reinvigoration of the North American Great Plains by using ecological restoration as the guiding principle for future development. Restored prairie addresses the problems of erosion and declining and contaminated water tables while providing economic opportunities both for high-quality ecotourism and for scientific research.

Prairie restoration is growing around the world. Severe dust storms in the Chinese grasslands, which caused extensive crop loss and animal deaths and damaged houses, have spurred restoration efforts there. Pilot projects involve collaboration between scientists and local communities to reduce animal-stocking numbers, to reseed overgrazed areas, and to reanalyze how the relatively new irrigation systems can be used strategically to support agricultural production without increasing erosion vulnerability. Russian restoration experiments date back to the 1960s. They remain small in scale and acreage, but, as elsewhere, interest and commitment to the effort are increasing.

PRAIRIES

Areas that were mostly covered with grasses and subdominant forbs (broadleaved herbs) prior to human intervention are known as *grasslands*. Extensive tracts of these grassland ecosystems in the drier interiors of continents, particularly in North America, are known as *prairies*. Grasslands occur where there is not enough precipitation to support a forest but there is enough for herbaceous plants. The grasses and lack of precipitation are just two of the characteristics that set apart the prairies from the other ecoregions of North America.

The beginnings of the North American grasslands occurred during the Miocene-Pliocene transition, perhaps 5 million to 7 million years ago. This time period is associated with widespread drying. The increased aridity resulted from the cooling of the oceans as the Antarctic ice sheet spread and from the uplift of the Rocky Mountains. The mountains provided a partial barrier against the moist Pacific air.

There is limited precipitation in this central region, with very warm ground and air temperatures in the summer and extremely cold temperatures in winter. The prairies extend several hundred kilometers, from north-central Mexico to the southern sections of the Canadian provinces of Alberta, Saskatchewan, and Manitoba. The terrain is most often level, though it may also include rolling topography such as the Flint Hills, which stretch from north-central Oklahoma to the north-eastern section of Kansas. Prairies are often categorized into three types: short-grass prairies, tallgrass prairies, and mixed-grass prairies.

The western sections of the prairie consist primarily of short grasses, which often grow in tufts. In this region, temperatures are higher in summer than in the prairies to the east, and the annual precipitation may fall below 25 centimeters. The grasses are generally less than 0.65 m (meters) in

height and can adapt better to occasional drought conditions and extreme temperatures. This type of prairie is often found not only in the semiarid climate of the Great Plains of North America but also in Eurasia, where it is referred to as *steppe*.

Tallgrass prairies once covered 140 million acres of North America, but now only 4% remain. These prairies are predominantly composed of taller grasses, sometimes reaching a height of 2.5 m. These grasses also have extensive and deep root systems. Nutrients have a stronger tendency to remain in the soil rather than leaching, since there is less rainfall here than in the forests. The intricate root systems are very efficient at using whatever water is available. The roots also stimulate carbonates and other nutrients such as calcium and magnesium to join the humus-rich surface layer.

A mixed-grass prairie is a landform where the grass composition is constantly shifting between tall and short grasses. This species transformation occurs as climate, precipitation, fires, and frequency of grazing vary from season to season.

North American prairies developed under the influence of grazing by a diverse group of native herbivores. Because the growth of grasslands is linked with a rise in the number of grazing and browsing animals, the association of grasses and grazers is most likely an ancient one. Several commonly known inhabitants were deer, antelope, and vast herds of bison that liberally fed themselves as they roamed. However, their constant nibbling did not destroy the grasses. Unlike woody plants, grass plants adapt well to grazing. The growing tissues in grasses are found at the base of the leaves near the ground surface. Therefore, when animals graze on the leaf blades, the continued growth process of each plant is protected. The adjacent forbs also survive because they may have thorns, tough structures, or simply a bad taste that discourages grazing.

Prairies also developed under the historical effect of fires, some set by Native Americans and some occurring naturally, such as those sparked by lightning. These fires removed predators and undesirable insects. Fires provided the necessary disturbances to deter the growth of invasive woody species and encouraged the increased growth of grasses and forbs in the North American prairies.

Temperatures in the prairies change seasonally, from extreme heat in the summer to bitter cold

in the winter. The winters can bring powerful blizzards, particularly in the Northern United States and in Southern Canada. With blizzards in the winter, droughts in the summer, and precipitation varying so much from year to year, it can be difficult to place the prairies into firm climatic categories.

Pioneer wagons on their way west most often passed through the grasslands, because the elevation change was gradual and travel easier over the level terrain. However, they seldom stopped to settle, because farmers from the east were accustomed to plenty of water for their crops and animals and were not readily prepared for the overall dry conditions. They were also used to an abundance of wood for building, fencing, and heating, and in the prairies, wood was scarce.

Between 1825 and 1865, rainfall was low in much of North America but especially in the central portion. Storms with high winds, hail, and tornadoes were common. In the winter, there were cold temperatures and blasts of wind that produced immense snowdrifts. Much of the prairie was too difficult to farm. The grasses' strong root systems made it extremely difficult to plow the land, and some farm implements that normally took one or two animals to operate often required the strength of numerous animals. For housing, however, settlers were able to use large bricks cut from the prairie sod to construct durable and sturdy homes.

In 1837, John Deere invented the steel plow, which made it possible to break apart the strong roots of the thickly interlaced sod. Barbed wire was developed in the 1870s, giving the rancher an alternative to the traditional wooden fence. The wet and dry periods continued, but with the expansion of the railroad and numerous agricultural innovations, such as the steel plow, more people were able to cultivate the land. The population increased, and human activity brought additional changes to the grasslands.

After the end of World War I and following several years of adequate rainfall, a wave of new farmers moved into this region. As agricultural activities increased, much of the grasslands were transformed to grow crops. At the same time as plowing increased, dry weather ensued, and with the previous deep root systems removed, the topsoil began to erode at alarming rates. Winds brought dust storms that would last for several days.

Williams Prairie, part of the 14 preserves west of Houston, Texas, that are managed by the Katy Prairie Conservancy

Source: Katy Prairie Conservancy/Wikimedia Commons: http://commons.wikimedia.org/wiki/File:Williams_Prairie.JPG.

For 3 days in March 1935, the department of geology at the University of Wichita (now Wichita State University) in Kansas “weighed” the atmosphere. Over the city and surrounding region, they studied an area of 78 km² (square kilometers), scanning up into the atmosphere approximately 1.5 km. The scientists estimated that 4.5 million metric tons of dust was suspended over this one area. From 1933 to 1935, a time of many “dusters” (as the storms were often called), an estimated 150,000 people moved out of these central states.

Today, however, the land is again sustained with crops such as wheat and corn. Range managers work to preserve the prairies in areas such as Wind Cave National Park in South Dakota and the Tallgrass Prairie National Preserve and the Konza Prairie, both in Kansas. Controlled fires are set in the early spring to increase grass productivity and help control nonnative invasive plants. Large grazing animals are used to promote the long-term diversity of plant species. Together, these two

ancient activities are being used to ensure that there are healthy grasslands for the future.

PRECIPITATION, GLOBAL

Precipitation is the principal link between global water and energy cycles, weather and climate, and the activities of humankind. Natural and anthropogenic processes can alter the frequency, distribution, and magnitude of precipitating weather systems (e.g., the El Niño Southern Oscillation, urban heat islands, and deforestation). Changes in precipitation characteristics can affect Earth's energy balance through the redistribution of solar and terrestrial energy and latent heat fluxes. Planetary atmospheric circulation is largely driven by Earth's energy balance; thus, global precipitation patterns are a key element in climate variability. Therefore, the critical task is to continue to develop methods that allow for consistent, high-quality global observations of precipitation in order to gain better insight into the Earth system and weather and climate variability through improved forecasts. This entry discusses in situ measurements and remote sensing techniques used in the study of precipitation processes.

In Situ Measurements

Given that precipitation processes often evolve rapidly and are stochastic in nature, our understanding of their characteristics is limited in part by our ability to observe and accurately represent precipitation over a variety of time and space scales. This is especially true for developing countries and remote regions around the world, including equatorial (e.g., Amazonia, South America) and oceanic regions, where in situ observational (rain gauge) networks are severely limited. In addition to the insufficient global density of rain gauges, other drawbacks are that rain gauges are point measurements that often fail to effectively represent precipitation variability across relatively large areas. For example, it is not uncommon for a single thunderstorm to produce intense rainfall over an area that is not covered by rain gauges, systematically missing out on the occurrence of precipitation. Unfortunately, any sufficiently large rain gauge network would likely be highly expensive and impractical to implement. Other effects such as wind, evaporation, and water sticking to the side of the gauge can lead to underestimation of precipitation. Furthermore, there are often inconsistencies among rain gauge types and in calibration efforts.

Despite these pitfalls, one very important advantage of the use of rain gauges is their use of a metric that is based on the actual collection of precipitation. Another advantage includes excellent temporal sampling. Ultimately, rain gauges alone cannot adequately represent global precipitation due to the lack of coverage in the major part of the world. But since rain gauges physically measure precipitation at the surface, these instruments remain very important with respect to the verification and calibration of other instruments and approaches, including radars and satellites.

Remote Sensing Techniques

In an attempt to compensate for the deficiencies of rain gauges, the use of active and passive remote sensing techniques has steadily increased since the mid to late 20th century. While the use of remote sensing often increases the spatial sampling of precipitation (when compared with in situ observations), this approach is not without limitations. The primary disadvantage is that the radiometric properties of precipitating systems are used to infer the occurrence and intensity of precipitation. These inferences are algorithmically derived from various cloud attributes, including cloud-top temperatures, cloud-type and height discrimination, and the emission and scattering properties of hydrometeors, among others.

Active Microwave

Many surface-based radar systems now have the capability of sampling 0.25 km (kilometer) by 0.5° at a range of 300 km (e.g., WSR-88D Super Resolution), with a temporal sampling frequency on the order of minutes. However, similar to rain gauges, surface-based radars' precipitation estimates are limited near shorelines, over the oceans, and in remote regions around the world. While a mosaic of surface-based radar coverage can reach much of the area that is not covered by rain gauges, certain topography (e.g., mountainous areas) can hinder the radar's ability to sample a full swath (Figure 1). Surface-based radars also typically rely on a transformation factor that relates the poor physical connection of radar reflectivity (Z) to precipitation rate (R), which has been shown to produce considerable error in precipitation estimates. Additional sources of uncertainty in surface-based radar estimates stem from signal calibration and

Figure 1 Radar-estimated accumulated precipitation for the United States on May 30, 1998

Source: National Aeronautics and Space Administration.

corrections required for anomalous propagation, attenuation, ground clutter, and beam filling. While surface-based radars' precipitation estimates provide an excellent supplement to rain gauge observations, the majority of the world's precipitation remains unsampled by these instruments due to their fixed position, limited sampling range, and relatively high operation and maintenance costs. With these concerns, scientists have developed a suite of space-based approaches to examine precipitation around the world.

Visible and Infrared Radiation

Since clouds are opaque to visible and infrared (VISIR) radiation, VISIR methods use various cloud attributes as a proxy for precipitation estimation. Specifically, the algorithms used to indirectly estimate precipitation from VISIR radiometers on board geosynchronous satellites (e.g., Geostationary Operational Environmental Satellite [GOES]) relate cloud-top reflectivity and brightness temperatures (a metric of radiation in the form of the temperature of a blackbody object with equal emittance of radiation at a given wavelength) to cloud height and thickness and precipitation rate. Following this logic, heavier (or less or no) precipitation is inferred

from colder (or warmer), brighter (or less bright) clouds. These assumptions can sometimes work well with deep convective storms. However, the primary flaw is that VISIR approaches often have difficulty discriminating between relatively warm, wet clouds (e.g., stratus) and cold clouds with no precipitation (i.e., cirrus). This can be especially problematic for convective complexes beneath a unified cirrus canopy.

Many VISIR techniques have been developed to address these concerns and help improve the accuracy of these indirect approaches. In one method, cloud indexing derives the probability and intensity of precipitation from different classes of clouds or temperatures (e.g., the GOES Precipitation Index [GPI]). Bispectral methods combine radiances from cold, bright and warm, dark clouds to determine precipitating and nonprecipitating clouds. This method is particularly useful for identifying cirrus clouds. Life history methods relate precipitation intensity as a function of the growth and decay of the cloud system. Other cirrus and low-level cumulus discrimination methods include the use of split-window channels (11 and 12 micrometers). Cloud models attempt to replicate cloud microphysics in an attempt to differentiate between convective and stratiform precipitating systems.

While VISIR approaches lack direct observation of precipitation processes, these approaches benefit from relatively good spatial and temporal resolution from geosynchronous satellites. Specifically, VISIR precipitation data are typically available every 15 minutes, with spatial resolutions of 4 and 1 km, and are best suited for larger-scale climatological precipitation studies.

Passive Microwave

Precipitation particles (water droplets and ice crystals) are the primary source of attenuation of a passive microwave signal. Therefore, rather than inferring precipitation processes from cloud-top characteristics, passive microwave instruments provide a more accurate portrayal of instantaneous surface precipitation, given that microwave radiances (hydrometeors) are directly sensed within the cloud.

Two fundamental algorithms are used in passive microwave-estimated precipitation. The first deals with the absorption and emission of water droplets in clouds, whereby precipitation intensity varies as a function of brightness temperature differences. Relatively warm brightness temperatures stem from the emission of numerous water droplets and are linked to greater precipitation intensities. Likewise, relatively cool brightness temperatures are associated with little or no precipitation. Therefore, the emissivity of cloud liquid water droplets and the associated precipitation is best discerned over regions with relatively cooler backgrounds (i.e., oceans). Given that the emissivity of ocean and land is 0.4 to 0.6 and 0.8 to 0.9, respectively, the pitfall with this algorithm is that low-frequency channels (i.e., <22 GHz [gigahertz]) generally fail at discerning precipitation processes over land surfaces with similar emissivity properties.

The second algorithm uses high-frequency channels (i.e., 85 GHz) to detect ice scattering within the cloud. Heavier (or little or no) precipitation is associated with relatively cooler (or warmer) brightness temperatures, that is, with greater (or little or no) scattering. Since the ice-scattering signal is independent of surface effects, the application of this algorithm is universal for land and ocean. However, ice-scattering algorithms are not sensitive to warm-cloud precipitation processes and are best suited for convective precipitation processes.

Figure 2 TRMM-accumulated 3-hourly rainfall estimates for January 27, 2010, at 1200 Coordinated Universal Time (UTC)

Source: National Aeronautics and Space Administration.

While passive microwave instruments (e.g., the Special Sensor Microwave/Imager [SSM/I], Advanced Microwave Sounding Unit [AMSU], Advanced Microwave Scanning Radiometer-Earth Observing System [AMSR-E], and Tropical Rainfall Measuring Mission [TRMM] Microwave Image [TMI]) provide a more direct inference of precipitation when compared with VISIR approaches, these instruments suffer from poor sampling frequency aboard polar-orbiting satellites. Depending on the frequency channel, the spatial resolution from passive microwave precipitation estimates ranges from 5 to 40-plus km. Moreover, microwave sensors often experience beam-filling issues with precipitation and land surface features.

Blended Techniques

In a continuous effort to minimize the deficiencies and errors associated with single-sensor/instrument methods and to increase the spatial and

temporal sampling of precipitation around the globe, scientists have concentrated on multisensor/instrument approaches. The idea is to use the advantages of each approach (e.g., direct observation from rain gauges, excellent sample frequency from VISIR, and better accuracy from passive microwave estimates) to develop a “best” estimator or high-quality determination of precipitation processes around the world. Some specific examples of various techniques used to derive blended precipitation products include the TRMM Multi-Satellite Precipitation Analysis (TMPA), Climate Prediction Center Morphing Method (CMORPH), Hydro-Estimator, Naval Research Laboratory Global Blended-Statistical Precipitation Analysis (NRLgeo), Precipitation Estimation From Remotely Sensed Information Using Artificial Neural Networks (PERSIANN), Passive Microwave-Calibrated Infrared algorithm (PMIR), Global Precipitation Climatology Project (GPCP), and Adjusted GOES Precipitation Index (AGPI). Given multiple precipitation observation sources, one problem inherent in blended or merged precipitation products is that operational errors from a single data source can considerably reduce the accuracy of the end precipitation product. For intercomparisons and validation studies of

multisensor/instrument approaches, the reader is encouraged to consult the efforts put forth by the Program to Evaluate High Resolution Precipitation Products (PEHRPP).

One of the goals of blended precipitation products is to globally observe precipitation using passive microwave sensors with a sampling frequency similar to that of VISIR instruments. Eliminating the inference of precipitation based on cloud attributes and moving to a physical-based passive microwave product would increase the accuracy of precipitation estimates. One international program that is devoted to achieving better accuracy of global precipitation is the Global Precipitation Measurement (GPM) mission.

The foundation for the GPM mission stems from the success of the TRMM. One of the objectives of TRMM during its launch in December 1997 was to use a multisensor/satellite approach to collect relatively high spatial and temporal resolution precipitation data for poorly sampled regions around the world (viz., the tropical oceanic regions). With the success of the TRMM, precipitation data are available every 3 hours, globally between 50° N and 50° S (0.25° × 0.25° resolution) from January 1998—near real time (TMPA 3B42, Version 6) (Figure 2).

Figure 3 Schematic overview of Global Precipitation Measurement

Source: Japan Aerospace Exploration Agency.

The GPM mission is the next generation suite of satellites aimed toward improving our understanding of global precipitation and its effect on the natural environment, by using a constellation of passive microwave radiometers, and the first space-based Dual-Frequency Precipitation Radar (DPR; TRMM contains the first space-based single-frequency precipitation radar). Combined with the onboard microwave imager Global Mapping International (GMI), the GPM mission will improve on the capabilities of the TRMM by providing full global coverage of precipitation, with the additional ability of measuring relatively lighter rainfall and frozen precipitation (Figure 3).

While passive and active sensors on board geosynchronous satellites are considered optimal for observing global precipitation, the technological limitations of such an approach mandate missions such as GPM. The launch of GPM is currently slated for 2013 to 2014.

PRECIPITATION FORMATION

The formation of precipitation is a complex process by which suspended atmospheric moisture in the form of very small cloud droplets ultimately transitions into the larger frozen or nonfrozen precipitation observed at the surface. This entry describes four aspects of precipitation formation. First, the presence of a lifting mechanism is necessary to lift the air vertically. Second, condensation or ice nuclei are essential for the formation of precipitation in the atmosphere. Third, there are two fundamental processes by which precipitation forms; both of these processes are described and referenced by their typical geographic locations of occurrence. Finally, the unique formation of particular precipitation types is discussed.

Processes of Precipitation Formation

Some type of lifting mechanism is required to create rising air, which leads to cloud and precipitation formation. In the absence of a lifting mechanism, it is possible to experience light precipitation such as mist or a drizzle. Four common lifting mechanisms are (not in order of importance) convection, convergence, orographic, and frontal. Convection refers to the vertical transfer of heat energy through rising buoyant air near the surface. It is an important warm-season lifting mechanism leading to precipitation formation. Convergence refers to the lifting of air when there is an inflow of air into a region near the surface. Its spatial scale is normally larger than convection, but convergence is generally a weaker lifting mechanism than convection. Orographic lifting occurs when air is forced to ascend a mountain barrier, thus resulting in condensation and precipitation on the windward side of the mountain. Frontal lifting can occur with a variety of weather situations, but it is most common with a migrating wave cyclone where contrasting air masses are colliding.

If a lifting mechanism is in place, the next ingredient is something solid for tiny cloud droplets to attach onto. Condensation nuclei are small atmospheric particles (0.2 μm [micrometers]) with normal atmospheric concentrations ranging from 100 to 1,000 nuclei per cubic centimeter. They are composed of many different substances, with the most common being sea salt, dust (clay and silt), and gases such as sulfur and nitrogen oxide. They can be divided into two types: (1) hygroscopic, or attracted to water, such as sea salt and sulfates, and (2) hydrophobic, or water repellant, such as soot and organic carbon. They are vital to the precipitation process because water in the form of cloud droplets (20 μm) requires a nongaseous surface to attach and transition from the gas phase to the liquid phase. Cloud condensation nuclei attract cloud droplets, and droplets then grow in size through coalescence, becoming larger cloud droplets (100 to 500 μm) and possibly raindrops (2,000 μm). The processes by which cloud droplets grow into raindrops are described in more detail in the following paragraph on precipitation formation processes.

There are two established processes by which precipitation forms: (1) collision and coalescence

and (2) Bergeron/Findeisin. Although these two processes have fundamental physical differences, precipitation frequently forms (especially in the midlatitudes) as a result of both processes working in unison. In the midlatitudes, precipitation may initially form as a result of the Bergeron process and then undergo collision and coalescence closer to the surface.

Collision and coalescence is frequently referred to as warm weather precipitation as it occurs in atmospheric temperatures $>0^{\circ}\text{C}$. Naturally, this process is common in the tropics and subtropics for much of the year, and it is also common in the midlatitudes during the warmer months. During collision and coalescence, larger cloud droplets begin to acquire higher terminal velocities. As the fall speed increases for the larger droplets, they become collectors of smaller droplets through collisions. However, as the collector droplet falls, air resistance may split the droplet into several smaller droplets, thus recycling the process back to its beginning. When the larger collector droplets have attained a sufficient size and velocity to offset the rising motions within the cloud, precipitation then falls to the surface in the form of rain.

The Bergeron/Findeisin process (commonly referred to as Bergeron Process) best explains precipitation formation at mid and high latitudes, where a large portion of the atmosphere is $<0^{\circ}\text{C}$. The coexistence of ice crystals and supercooled water (water in liquid state albeit $<0^{\circ}\text{C}$) is important for the Bergeron process. Water can exist in a supercooled state if there is no condensation or ice nuclei present for the water to attach to. This is common in the upper troposphere, where condensation nuclei are scarce. When ice and supercooled water coexist, the ice crystals function as ice nuclei and will grow at the expense of the water droplets. This is because the saturation vapor pressure is lower for ice than it is for water at temperatures below freezing. In the Bergeron process, precipitation initially begins as snow before undergoing transitions based on the temperature profile of the atmosphere.

Types of Precipitation

Depending on various combinations of synoptic scale weather patterns and the vertical temperature

profile of the atmosphere, a variety of precipitation types may fall to the surface. The most fundamental type of precipitation is rain, which is observed at the surface when there is a deep vertical layer of air $>0^{\circ}\text{C}$. In contrast, snow is observed at the surface when there is a deep vertical layer of air $<0^{\circ}\text{C}$. Sleet is observed at the surface if precipitation initially falls as snow in the upper troposphere and then encounters a shallow melting layer or more than one melting and freezing layers in the middle troposphere before partially regaining some of its crystal structure as it approaches a surface near or just below 0°C . Freezing rain or glaze forms if precipitation initially falls as snow in the upper troposphere but then encounters a deep melting layer in the middle troposphere. As terminal velocity increases in the melting layer, the rain does not have time to refreeze in the $<0^{\circ}\text{C}$ layer of air near the surface. The supercooled water then freezes on contact with the surface, creating hazardous conditions.

PRED, ALLAN (1936–2007)

Allan Pred was a longtime professor of geography at the University of California, Berkeley, and one of the discipline's leading practitioners of urban geography and social theory. Pred's

career took him through diverse conceptual approaches in a series of shifts that both reflected and contributed to geography's intellectual transformations.

In the 1960s, Pred's work centered on the historical geography of American manufacturing and its linkages to the country's urban growth patterns. His perspective was resolutely historical, emphasizing the contextualized nature of urban growth rather than abstract processes independent of historical time. Increasingly, the early focus on manufacturing was supplemented by a growing interest in the role of information and its relations to the differential growth of cities. Much of this phenomenon was theorized in terms of circular and cumulative feedback loops. In particular, he noted the powerful role of the telegraph in the long-distance transmission of information in the 19th century, a technology that greatly reduced uncertainty and accelerated the penetration of the Midwestern regions by east coast capital.

In the 1970s, Pred turned toward the time-geography initiated by Torsten Hägerstrand and began to apply this framework to the U.S. context. Places, he maintained, are always and everywhere times—that is, always coming into being—and geography can never be fruitfully portrayed as a static landscape frozen at one temporal moment. This move led him on the one hand to delve more deeply into issues of individual consciousness, including the notion of sense of place advocated by humanistic geographers, and to integrate individual life trajectories with broader questions of social reproduction on the other.

Pred became a fierce advocate of Anthony Giddens's notion of structuration and worked assiduously to integrate it with geographers' notions of place and locale. In this reading, the socialization of the individual and the reproduction of society and place are two sides of the same coin—that is, the macrostructures of social relations are interlaced with the microstructures of everyday life. For Pred, people reproduce the world, largely unintentionally, in their everyday lives, and in turn, the world reproduces them through socialization. In forming their biographies every day, people reproduce and transform their social worlds primarily without meaning to

do so; individuals are both produced by and producers of history and geography. Because people are endowed with the capacity to resist hegemonic power relations, the production of places is always contingent. Empirically, Pred offered applications to Boston, examining the lives of merchants in the 19th century as the city was catapulted through waves of mercantile capitalism, industrialization, and a rapidly changing world economy.

One facet of this line of thought led Pred to a sustained concern for the role of language in the making of place and people. As a set of representations of the world that simultaneously shape consciousness and define the meanings given to place, language came to assume a central role in his analysis of social reproduction and local politics.

Historical context, the world economy, time-geography, structuration, and language were all parts of his ambitious analysis of 19th-century Stockholm. Having spent considerable time in Sweden, with access to its rich census data, Pred traced the contingent reconstruction of the city's streets and neighborhoods as an emerging bourgeois identity was firmly imposed on its landscapes, both annihilating older, preindustrial meanings and simultaneously defeating alternative, working-class ones. This project lay at the core of a broader agenda to uncover the historical roots and implications of modernity in general.

Pred's fascination with Sweden included a growing critical strain. Even in ostensibly the most tolerant of societies, he argued, racism was widespread. Pred thus became a pioneer in geography's examination of ethnicity and race, which, under the impact of poststructural critiques, revealed race to be a set of economic, political, cultural, and discursive relations that shape individual and collective life chances and identity. By contextualizing race as an ideology, as a socially constructed relation, not a biologically determined "given," Pred illustrated the complex ways in which race is constructed, experienced, and negotiated in everyday existence; how it intersects with class and gender; and the manner in which racial relations of domination and subordination play out over space and time. Like gender, racial and ethnic identity

is fundamentally a power relation that typically reflects, reinforces, and naturalizes existing lines of inequality.

their population sizes, spatial extent, or territorial size and the importance of their economies. Primate cities are the largest cities in their respective countries, as they dominate the economy as well as being the top ranking in terms of territorial extent and population size. Geographer Mark Jefferson coined the term in the 1930s and defined a *primate city* as one that is twice as large as the next largest city in the urban hierarchy of a country and twice as significant economically. A primate city also dominates in terms of the centralization of the country's transport and communications, industrial and commercial institutions, trade, education, culture, and other phenomena.

Primate cities around the world tend to be many times larger than the next largest cities in their respective countries, including London (about six times the size of the second largest city) and Paris (about eight times the size of the next largest city). Other examples from the developed world include Copenhagen, Prague, Budapest, Vienna, Brussels, and Dublin. In the developing world, Bangkok, the capital of Thailand, is at least 35 times the size of the next largest city, Chiangmai, in terms of population. Bangkok's economic role is even more significant, and this primate city is believed to generate half of the country's jobs and gross domestic product. Other developing country examples include Addis Ababa (Ethiopia), Lagos (Nigeria), Kampala (Uganda), Bogotá (Colombia), Jakarta (Indonesia), Baghdad (Iraq), Tehran (Iran), Manila (Philippines), Mexico City, and Buenos Aires (Argentina). Primacy in the urban hierarchy is seen to reflect uneven development in a country, with a highly developed metropolitan core or center surrounded by peripheral areas that are lagging behind in economic and social progress. These areas largely serve to provide the material resources and labor supply to the primate city.

There is no single cause for the development of primate cities, since they are not necessarily confined to developing countries. Yet many of the developing countries with such primate cities have been European colonies, where these cities served as the gateways to the natural wealth being exploited by colonial administrations. These administrations concentrated the

PRIMATE CITIES

development of infrastructure and services such as rail transport and ports in these primate cities. They may be areas of substantial agglomeration economies as well.

Primate cities, because of their sheer size and the economic activities concentrated in them, serve as magnets to migrants from rural areas and smaller cities or towns. Many are attracted by the promise of better economic opportunities and lives in the primate cities. Such migration has added to the primacy of the cities, many of which are capital cities as well as cities that have grown beyond their earlier administrative boundaries. Bangkok is a metropolitan region extending into surrounding areas through sprawl and suburbanization as well as peri-urban growth. This process has been encouraged by businesses and households seeking to escape the congestion and related problems

such as pollution, inadequate housing, and traffic jams in the inner-city areas.

PRIVACY AND SECURITY OF GEOSPATIAL INFORMATION

The concept of privacy of geospatial information pertains to the amount of personal or otherwise sensitive information that can be gleaned directly from the contents of one data source or indirectly when one source is analyzed in combination with other data sources. The concept of security of geospatial information relates to the set of rules or practices that enforces who can access what data, under what circumstances, and by what means. The collection, storage, dissemination, and use of geospatial information are often seen as requiring special care with regard to both of these concepts because these data are highly descriptive and often contain personally identifying or potentially damaging, dangerous, or sensitive information. The wide variety of types, uses, and content of geospatial information requires that notions of privacy and security cover a vast range of topics, including an individual's right to privacy and control over information about herself or himself, the rights of scientists to obtain and use information on behalf of the public good, and the rights of governments and organizations to guard information from public view. Each of these is a contentious issue that has been debated since well before the introduction of digital geospatial data. However, with the advent of modern geospatial information techniques and technologies, these issues continue to gain ardent and vocal supporters on all sides.

At the individual level, privacy and security are issues with regard to geospatial information because these data often contain personally identifiable information along with the characteristics of an individual or group. Because geospatial information consists of sensitive data, many people view the collection, storage, and dissemination of these data as infringing on an individual's right to privacy. Essentially, this issue is an extension of

the personal privacy debate into the geospatial information domain. This has been driven for the most part by the ease with which geospatial information can be easily linked to other forms and sources of information about individual or group characteristics and processed rapidly in huge volumes with digital techniques. The application of geodemographics to product marketing has been at the center of the debate on the appropriateness of this practice since its inception. However, as geospatial data and services become increasingly available and mainstream, individuals and policy-makers will be confronted with trade-offs between personal convenience and potential loss of personal privacy. Location-based services are a direct example of this because they have the potential to provide highly tailored, timely, and useful data and services but require that an individual surrender a portion of his or her personal privacy to facilitate the process.

Many in the public service and health sectors view the availability and use of geospatial data at the individual level as essential to public security, health, and welfare. Geospatial information containing personally identifiable information and characteristics is seen by many as key to stopping crime and reducing the burden of diseases on society. For instance, in some cases, criminals are required by law to register their places of residence within geospatial databases. The public availability of these data is thought by some to thwart potential future crimes by raising public awareness, thereby increasing the public's security at the potential cost of the criminal's personal privacy. Similarly, some federal and state laws mandate the collection and submission of personal-level health-related geospatial information to disease registries. Some argue that beneficial outcomes such as the identification of pandemics and the advancement of scientific knowledge about the cause, treatment, and prevention of diseases would not be possible without the collection of individual-level, highly private personal data at the level of completeness and accuracy that the mandates were designed to facilitate. However, not all patients are aware of these disease surveillance practices using geospatial information derived from their personal records, and it is likely that not all patients would have consented had they known.

From the perspective of a data consumer, the privacy and security of geospatial information are sometimes seen as a hindrance. For example, to protect personal privacy, health-related geospatial information is not typically released to researchers without clear conditions and restrictions on who may obtain it and for what purposes it may be used. Furthermore, the display of these data in tabular or graphic form must typically meet requirements of anonymity, and geographic masking techniques are therefore required to be applied. Data release is a particularly contentious issue with regard to geospatial information created through the use of public funds by governments and organizations at the federal, state, and local levels. Many who wish to obtain these data feel that they should be made available to all citizens at the cost of reproduction, while others feel that charging a premium for these data is justified to support the ongoing costs of their production, storage, and upkeep. There are other forms of data that some feel should be completely out of the realm of public consumption due to the inherent public security concerns their release could foster. In all situations, the trade-offs between geospatial data privacy and security and scientific knowledge and public welfare must be weighed carefully when determining the suitability of their release.

PRODUCER SERVICES

Producer services are a set of industries that have markets primarily with businesses and governments, as opposed to markets mostly with households. These services include accounting, engineering, architecture, legal services, real estate, insurance, financial services, management consulting, advertising, design, administrative support services, temporary help, and research. In contrast, services such as retail trade, health care, education, repair of automobiles, and movie theaters have households as their primary source of demand. There are varying definitions of producer services; some include parts of transportation services and real estate and insurance. Clearly, some industries that are dominantly part of the producer services sector also have household markets, such as legal and banking services.

Producer services have grown rapidly in recent years, employing 40 million people in the United States in 2006, or approximately 23% of the civilian labor force. This number has risen from 9 million in 1969, when producer services accounted for 10% of the civilian labor force. The United States has a relatively high fraction of its labor force in producer services, compared with some other advanced economies and compared with most developing countries. In part, this growth is due to the tendency for open-market procurement of many of these services in the United States, whereas in countries such as Germany, there is a tendency for more of this type of work to be performed in-house in manufacturing and service industries.

Much producer service work is unstandardized, requiring face-to-face meetings between clients and suppliers and between subcontractors. For example, a firm developing architectural drawings for a client may need to meet on the construction site to discuss possible approaches to development. A management consultant needs to come to the offices of the client to assess their consulting needs. An engineering firm may need to work with an architect to conceptualize alternative ways for designing a particular structure—in conference settings, in conversations on the telephone, via e-mail, or on the ground at a project site. Frequently, this work involves documents that get revised numerous times as tasks or projects are conceptualized from preliminary visions to final articulations. While the Internet and digital means of communication have made it possible to manage these logistics more efficiently, the creative element in face-to-face meetings is still an important part of the work in this part of the economy.

There are various explanations for the relatively rapid growth of producer services as a share of total employment. One argument is that there is low productivity in these services compared with other sectors of the economy, partly because the ability to increase labor efficiency in work that involves face-to-face creative effort is restricted. Another argument is that firms have outsourced work that they previously undertook in-house. Every business faces the “make or buy” decision, and some argue that businesses have chosen to turn to an outside contractor who can supply producer services at a lower cost than can be provided in-house. However, evidence is mixed on this behavior, especially when there is a very careful definition of the type of services that were produced in-house versus those that are being procured in the open market. Research shows that another force at work is the increasing complexity of service provision, related to the development of new and more detailed or sophisticated service concepts, often driven by advances in information technologies intimately related to the production and delivery of producer services.

A good illustration of how information technologies have changed service provision may be given with regard to accounting services. In the precomputer era, accountants used mechanical

calculators to derive balance sheets and profit-and-loss statements for their clients. Today, the clients can use accounting software to produce these documents for themselves, but they need accountants to advise them on the legal aspects of their bookkeeping practices as well as to give them financial management advice. The knowledge base used by accountants has changed, as have the capabilities of their clients. Also, government regulations require more independent audits.

In many cases, firms know that they need the specialized expertise available from a producer service firm and that they lack the capability to produce this specialized expertise in-house. The need for this service may be driven by government regulations or by the client’s perception that service providers should avail themselves of these specialized services. In other cases, the scale of demand for the specialized service is below the minimum size possible for an in-house department, leading firms to turn to specialized outside suppliers.

In yet other cases, there have been innovations in the supply of new services that were not produced in-house, and these have been adopted in the market. Examples abound in the use of computing services of these types of innovation, which have created huge markets for software giants such as Microsoft as well as tens of thousands of other niche market specialists.

Geography of Producer Services

Producer services have a very uneven geographical distribution. Headquarters functions of large corporations are a type of producer service, and they have been disproportionately concentrated in the largest cities, such as New York, London, Tokyo, and Frankfurt. Stock exchange functions and central banking also exhibit very high levels of concentration. More routine producer services, such as accounting or some types of legal services, are distributed much more broadly. There has been some de-concentration of the very highest-order producer services to suburbs and down the urban hierarchy, but this segment of advanced economies remains strongly agglomerated. Some argue that this clustering is due to the interactions needed between buyers and sellers in the face-to-face environment. Others argue that it is due to “nontraded interdependencies,” where expertise is shared

between individuals living in a city in environments ranging from bars to industry associations.

There is growing evidence that producer services can be traded interregionally or internationally, just like many categories of manufactured goods. This is particularly the case for “niche market specialists,” which constitute a sizeable share of producer service firms. These businesses have considerable locational freedom, often locating where their founder wants to live. Barriers to trade in producer services exist, in the form of licensing requirements, the need for practitioners to pass competency examinations, and differences in the business environment between nations and regions. Institutions such as the General Agreement on Tariffs and Trade (GATT) have been pressed to reduce these obstacles in recent years.

PRODUCT CYCLE

One of the more influential theories in economic geography in the mid 20th century was the product cycle, which integrated the supply and demand dimensions of corporate behavior and locations as they changed systematically over time. This view posits an idealized sequence in which goods move from being newly introduced innovations to becoming more widely accepted, until they finally reach a “mature” status. Different stages in the product cycle are associated with different market conditions, varying organization of production, and changes in geographic locations.

Drawing on the perspectives of innovation adoption widely used in marketing, this view begins with the changing nature of demand for a firm’s product over time, which is typically a bell-shaped curve, with new innovations adopted by a small group of risk takers. Adopters tend to be younger, more educated, and trendier than the population as a whole. As the product becomes better known and more widely accepted, larger numbers of more risk-adverse people will adopt it, sales increase, the market expands, and the firm can be confident of a consistent stream of future revenues. Finally, when the product becomes widely known, rates of new purchases will slow down as the market becomes saturated.

As the product proceeds through its cycle, the supply conditions change accordingly. With new innovations, where the information content is high, firms must expend considerable sums for research and development. Firms with monopolies over the production of products in their early years (e.g., as patent holders) may enjoy

superprofits for a limited time. Such companies tend to be relatively small, use higher proportions of skilled labor, and face a great deal of uncertainty in the market. Because they must produce in relatively small quantities, they are not likely to enjoy economies of scale and compete more on the basis of quality than price. Small firms in the early stages of the product cycle accept the market price—that is, they are price takers rather than price setters. As the product becomes more widely adopted and the market expands, firms can shift to producing larger quantities, standardizing the production process. As larger firms outcompete the smaller ones, the industry becomes more capital intensive in nature and more reliant on economies of scale, and the market becomes increasingly oligopolistic. Often, this transition is accompanied by a process of vertical integration, in which different stages of the production process become incorporated “in-house,” within the firm.

Raymond Vernon offered a series of geographic correlates for different stages of the product cycle. The original analysis was framed at the international scale, although subsequent ones extended this approach to national and regional ones. Thus, in the early stages of the product cycle, firms tend to prefer locations close to large pools of skilled labor, typically in economically developed countries. In subnational modifications of the product cycle, the optimal locations are in the cores of metropolitan regions, where firms can take advantage of agglomeration economies and dense networks of specialized contacts and information. Spatial cores are thus “seedbeds” of innovation. At the national scale, such locations were found in the traditional northeastern-midwestern Manufacturing Belt. As the product moves through the cycle, and the production process becomes more capital intensive, the need for centralized locations declines, and firms can relocate to the metropolitan periphery or, in the context of the national space of the United States, to the Sunbelt. Core regions are left to begin a new cycle of production by innovating in skilled, labor-intensive goods. Thus, the product cycle leads to the hypothesis that the decentralization of manufacturing is accompanied by the process of capital intensification as oligopolistic firms spin off their branch plants to peripheral locations in their search for cheaper and less skilled labor. At the

international scale, this process leads to multinational corporations investing in developing countries. This perspective sustains the view that exports from regions with comparative advantages early in the product cycle should be relatively labor intensive, while those with advantages later in the cycle should be more capital intensive. As product cycles play out continually over the landscape, markets will reproduce uneven development, in contrast to expectations that the free flow of labor and capital would result in a convergence of economic growth among regions.

Despite its comprehensiveness and appeal, the product cycle has been criticized as being simplistic. Although its description of the empirical nature of industrial change is essentially correct, the approach does not delve deeply enough into the dynamics of the production process, failing to embed it in any wider comprehension of social relations. Thus, it rests on an implicit notion of technological determinism. The model assumes that firms are single-product entities, always given over to capital intensification and vertical integration in a unilateral trajectory of growth and expansion, which is not always the case in practice.

PRODUCTION OF SPACE

Globalization has made it increasingly difficult to understand what is meant by “space” and “place” and how to delineate the two concepts. From a commonsense perspective, a region, a city, or a town may be seen as a “place.” But geographers have become critical of such an understanding. While physical geographers often work with a notion of absolute space, as if it were a merely objective, easily delineated and marked or mapped backdrop to life, in human geography there is a shift toward a notion of space as brought into existence by economic, political, and social relations.

This attention given to the social production of space by human geographers and the increasing popularity of this theme relate to globalization. Globalization brought about the idea that we have witnessed a time-space compression, a term introduced by David Harvey, who drew on Henri Lefebvre for the development of his arguments. Fast-travel possibilities, new media, and flows of capital and labor across the globe all affect the ways in which we experience and assign meanings to places as material sites.

Henri Lefebvre's Influence

Time-space compression stimulates the trend for different sites to become more alike (homogenization) and simultaneously also the need for distinction and specificity (differentiation). So instead of looking at objects and artifacts and even human beings in space, Henri Lefebvre (1901–1991) developed a theory of the social production of space that has heavily influenced most scholars who have tried to work with the idea that space is not but *becomes* in dynamic ways. To Lefebvre, there was not one understanding of space but a whole range of struggles over the meaning of space, especially in the framework of capitalism. Space, to Lefebvre, was a commodity: It was not defined by its physical attributes but as a product of capitalism. While globalization according to Lefebvre meant that each and every thing becomes subordinated to the workings of the capital market, countermovements aim to establish

alternative understandings of space, and hence, the result is an increasingly symbolically differentiated notion of space. Place, then, is a specific form of space produced through labeling and providing symbolic meanings.

This theme, developed later by geographers such as Doreen Massey, in terms of place making, and Anthony Giddens, as created space, thus criticized geography for taking space for granted and considering place as unproblematic. Now, many human geographers see places as those spaces produced by the lived experiences of people.

The Social Constructionist Perspective

Lefebvre, Harvey, and Massey worked on an understanding of space as socially produced, in relations and through inequalities understood through a neo-Marxist perspective. A second, albeit not fully independent, understanding of the production of social space can be traced in a sociological tradition influenced by social constructivism as developed by Berger and Luckmann. Especially since the 1960s, there has been an increase in attempts to analyze how urban meanings come about. The study of space as socially constructed has been central in cultural analyses that have focused on the city, as in Raymond Williams's work. Constructivism asserts that people make social life through their interactions. This is sometimes narrowly understood as verbal and nonverbal language. Often, it is understood more broadly as all patterns of everyday life and everything, including apparently “fixed” matters such as nature or the built environment and the meanings they have taken on, which are often taken for granted. Indeed, as Lefebvre maintained, practices and experiences create meanings just as much as does discourse. For the social production of space, then, this implies that the street corner, the plaza, and the urban neighborhood do not *have* meanings that are stable, obvious, and out there to be grabbed—for example, by the researcher—and that have clear-cut boundaries. Instead, they are seen as contested sites, where meanings are attributed through processes of appropriation.

This, concretely, means that police behavior, safety measures, and also expressions such as graffiti serve to determine symbolic ownership of sites that are inherently forming boundaries, including some and excluding others. While such processes are inherent to social life in general, the forms mentioned are those in which contestation becomes most obvious. Less obvious forms of the production of social meanings of places are those in which accounts of histories of, for example, neighborhoods or villages, focus on certain narratives while omitting others. They, hence, represent a partial account that feeds into a specific understanding of what a particular place “is.” Neighborhood reputations, especially when historically embedded and when emulated by their residents, are good examples of less obvious contested forms of appropriation of sites and thus of the production of space.

The Absence of Fixed Meanings

Finally, there are scholars who have attempted to figure out how to read urban spaces, such as Walter Benjamin. He concentrated in particular on how the everyday experiences of people give them a sense of the urban and how they hence develop an understanding of the city through the lens of their own life events. Along with Benjamin, many recent geographers and social scientists have thus argued that space has no fixed meanings that are inherent and monolithic but instead that people experience built forms and create memories while doing so; the meanings that they hence attribute to space may be very different from those intended by the designers of the physical spaces. From this perspective, then, spaces are inherently social.

PSYCHOANALYSIS, GEOGRAPHY AND

Psychoanalysis is a discipline founded by Sigmund Freud (1856–1939) at the beginning of the 20th century and subsequently developed by analysts such as Anna Freud, Jacques Lacan, Melanie Klein, and Donald Winnicott. Psychoanalysis consists of theories of human subjectivity and therapeutic practices that are primarily concerned with the amelioration of neurotic symptoms. It differs from conventional psychiatry and cognitive-behavioral therapies in its use of free association as a technique for accessing unconscious mental processes, its insistence on the importance of sexuality in the formation of psychical conflict, and its refusal to equate the ego with the subject.

In Freudian-Lacanian analysis, the analyst attempts to position himself or herself as a screen for the analysand's unconscious projections. Instead of engaging in conventional conversation, the analyst offers only enigmatic remarks

and polyvalent interpretations in an attempt to rouse the analysand's curiosity and bring his or her unconscious desire to the fore. The alleviation of psychical suffering that analysis aims for occurs through the eventual articulation of the analysand's unconscious desire. This includes the analysand's recognition of himself or herself as a "split subject"—that is, forever divided between the conscious ego and the unconscious, as well as by the gap between language and desire. For Lacan, analysis concludes only when the analysand comes to terms with his or her "fundamental fantasy," or the unconscious beliefs that structure the self's relationship to reality.

Psychoanalytic concepts such as the unconscious, the gaze, the Other, and the pleasure principle have had an indelible impact on the development of 20th-century literary theory, Marxism, feminism, postcolonialism, art history, and film criticism. Geography's engagement with psychoanalysis began in the 1990s with explorations of the spatiality of psychoanalytic categories such as the unconscious and discussions of the psychical dimensions of sociospatial phenomena. Psychoanalytic geography has thus far followed three main trajectories. First, geographers have used Freudian dream analysis to analyze cities through the unconscious desires and fantasies that create and sustain them. Geographers have also employed Freud's formulation of the Oedipus complex to illustrate how racial oppression under slavery was invested with repressed sexual desires within the slave-holding family. Second, geographers have used object relations theories to read sociospatial exclusions such as ethnic and economic segregation as part of processes of "othering," where dominant groups seek to produce a purified cultural "self" as against an excluded "other." In concert with this reading, geographers have looked to object relations' concept of "potential space," where children use objects such as pacifiers or blankets in ways that blur the distinction between self and object—interior and exterior—as a way of reconfiguring their understandings of space. Finally, geographers have drawn on Lacanian concepts of "extimacy," where subjectivity and emotions

are located outside the body, as well as his notion of "jouissance," which is enjoyment experienced as suffering, to explain how social phenomena such as violence and racism cannot be entirely reduced to social constructions but are always constituted through unconscious desire and anxieties about the Other.

More recently, some geographers have argued for the necessity of engagement with psychoanalytic methodologies. Some concrete proposals for methods have included "sandplay," where participants create a "potential space" by sculpting forms in sand with the researcher, to facilitate discussions of spaces and memory. Geographers have also debated using psychoanalysis to analyze interviews, though they have also cautioned that while psychoanalytic interpretation of interview data may be useful, geographers should not attempt to psychoanalyze their research participants.

The use of psychoanalysis within geography has been vigorously contested from a variety of positions. Critics have argued that psychoanalysis has been "tamed" through attempts to bring it into line with existing social-constructionist paradigms, while others have argued that psychoanalysis is masculinist, universalizing, and depoliticizing. While there certainly are politically problematic aspects in Freud's writings, most often products of the prejudices of his time, Freud's work has been used across the humanities and social sciences to destabilize fixed categories of gender and sexuality. Beyond Freud's own work, subsequent theorists and analysts have pushed psychoanalysis to the point of its auto-critique, forcing it to contend with the profound implications of an unknowable unconscious, a de-essentialized sexuality, and a radically indeterminate subjectivity.

PTOLEMY (AD 87–150)

Of all Roman intellectuals, Claudius Ptolemaeus, or Ptolemy, perhaps more than any other classical scholar, did the most to influence subsequent European notions of geography for the next millennium by dominating the popular and literary view of Earth throughout the Middle Ages. Little is known of his private life. Greek by birth, as were many scholars during the Roman Empire, he spent his career in Roman Egypt at the famous museum at Alexandria, then the epicenter of intellectual life. Ptolemy was, among other things, a mathematician, an astrologer, and an astronomer who studied optics and refraction; the Arabs later credited him with the invention of the astrolabe. His greatest work in this domain was the geocentric *Almagest*, or “Great Treatise” concerning the movement of the sun, moon, and planets, the only surviving ancient text on astronomy.

But his greatest fame was in geography, which he took to mean the description of Earth as a whole. He differentiated between *geography* as the study of universals, *topography* as the study of localities, and *chorography* as the means of integrating the two scales. Ptolemy ridiculed Strabo’s emphasis on individual regions, arguing instead for a holistic view encompassing the entire globe; he maintained that the regional emphasis was akin to painting a person by only showing his or her eye or ear.

In his famous eight-volume *Geographia*, a compilation of data about the geography of the Roman world, Ptolemy synthesized and extended

Hipparchus’s grid system of latitude and longitude for plotting the surface of the Earth, dividing it into 360 degrees and dividing each degree into seconds. It consists of the first known projection of a sphere onto a plane. The *Geographia* thus deployed a view of space as abstract, geometric, and homogeneous, invoking concepts derived from Euclidean geometry. He also attempted to map the known world with a map stretching from the Atlantic to China and speculated about the *terra incognita* (unknown territory). The *Geographia* became a canonical text in medieval Europe.

Although no Ptolemaic map survives, his descriptions formed the foundation on which the Western geographic imagination would be based well into the 16th century. His works were translated from Greek into Arabic in the 9th century and into Latin in 1406. During the Renaissance, Ptolemy, for all his errors, remained the chief classical authority to whom geographers turned in making sense of the newly unfolding world. When Columbus set forth on his voyage in 1492, it was Ptolemy’s conception of the world that he relied on, although Ptolemy’s estimate of the size of Earth was too small. Ultimately, however, colonial voyages of discovery and conquest put to rest Ptolemaic conceptions of Earth and opened the way for newer, more pragmatic accounts.

PUBLIC HOUSING

Broadly defined, *public* or *subsidized housing* is a federally funded effort to provide basic shelter and amenities for disadvantaged members of the population. It is a direct form of state intervention in which government housing authorities maintain property ownership and lease dwelling units to tenants at rates lower than the local private housing market.

In the United States, public housing grew out of public works programs initiated during the

Great Depression as a way to strengthen the economy. In 1937, the Housing Act was established to clear rapidly expanding slums and stimulate the construction industry. As part of Lyndon Johnson's Great Society legislation, the Department of Housing and Urban Development was created in 1965 as a cabinet-level agency to execute housing policy. Public housing was "established to provide decent and safe rental housing for eligible low-income families, the elderly, and persons with disabilities." Though ostensibly, this provision seems like an incontrovertible social good, historically, the geography of public housing has

The complex of white high-rise buildings in the center of the photo is the William Green homes, known as the "Whites." Completed in 1962, they were among the last of the 51 buildings that constituted the Cabrini-Green project. Most of the Cabrini-Green buildings were demolished amid controversy concerning the inclusion of mixed-income housing as part of redevelopment.

been much more complex. Public housing has proved to be a contested space articulating a highly uneven human geography deeply informed by race and class struggles. In particular, the specific location of public housing projects has tended to be an issue pitting the interests of government agencies, low-income tenants, and local private owners against one another. Historically, economic constraints and resistance from local community groups have forced public housing officials to place projects in urban areas near industrial zones, railroad tracks, and areas with high rates of crime and drug abuse, creating racially segregated ghettos, an involuntary process of de jure segregation.

In addition to the specific location of such housing, cost restrictions have tended to foster the construction of architecturally monotonous modern, high-rise towers, often labeled “the projects.” Sociologists have pointed to the palpable stigmatism associated with living in these emblematically dysfunctional areas. Though now largely considered anathema, the design of high-rise public housing projects often takes undue blame for the problems endemic to public housing. One iconic example perpetuating this notion is St. Louis’s infamous Pruitt-Igoe project. Designed by the architect Minoru Yamasaki in 1951, it was demolished in

the 1970s by the federal government after it fell to disrepair and vagrancy. Critics of those emphasizing the centrality of poor architectural design suggest that the reasons for the demise of Pruitt-Igoe and projects like it are much more complex and socioeconomically informed. Another image of the failure of U.S. housing policy is the Chicago Housing Authority’s Cabrini-Green housing project, most of which has been demolished and is being redeveloped. Cabrini-Green was popularly displayed on the 1970s sitcom *Good Times*. While putting forth a progressive social message in an aestheticized and distortedly large space, *Good Times* was paradoxically premised on a metanarrative of public housing or “the projects” as malfunctioning and as an object of ridicule. The weekly show functioned to normalize the living conditions within public housing while marginalizing that space and popularizing the notion that public housing was, indeed, a failed endeavor. With the global liberalization of economies from the 1970s onward, federal funding for public housing in many countries has dramatically decreased. Emphasis instead has turned to the creation of lower-density, mixed-income “projects” by public-private partnerships.

While public housing has largely fallen into disrepute in the United States and elsewhere, by

no means are these attitudes universal. Instead, public housing manifests itself differentially across diverse political geographies. Different cultures and their respective governments have varied views on public housing and implement policy in numerous ways. For example, in Singapore, where an overwhelming majority of citizens reside in government-run facilities, public housing generally does not carry the stigma and association with crime and poverty that it does in the United States. Conceptually, the provision of public housing can be seen as hinging on the question of whether or not housing is deemed a basic human right. How this debate is waged and manifests itself spatially constitutes the complex geography of public housing.

PUBLIC PARTICIPATION GIS

Public Participation GIS (PPGIS) is the use of geographic information systems (GIS) in efforts to broaden public involvement and influence in matters such as public policy, urban planning, environmental management, and rural development. Geographers engage with PPGIS as both a topic of academic research and an applied practice. While the roots of PPGIS are diverse, the term itself emerged in response to debates in the 1990s over the social, ethical, and political implications of GIS. Three related concerns, in particular, have had a lasting influence in the trajectory of PPGIS research and practice: (1) the antidemocratic implications of the growing role of GIS in

spatial governance and decision making due to inevitable disparities in access to data, technology, and expertise; (2) the ways in which the rigid data and representational structures of conventional GIS privilege and legitimize particular kinds of spatial knowledge while marginalizing others; and (3) the role of social, economic, and political power in shaping the social construction of GIS technologies and institutionalized practices. PPGIS scholars seek out ways to progressively address these problems in practice. Described below are three general approaches to PPGIS: (1) participatory GIS, (2) collaborative decision support GIS, and (3) Web-based grassroots GIS. Each is distinct with regard to the “public” it serves, the forms of “participation” it facilitates, and the objectives it seeks to bring about.

Participatory GIS

The first approach, often labeled *participatory GIS* (PGIS), involves explicitly working to empower groups that are marginalized rather than facilitating greater involvement among the public at large. Such efforts are often rooted in the theory and methodology of participatory action research, in that the GIS scholars and practitioners work *with* community members to both examine a social problem and work to create social change. For example, Trevor Harris and Daniel Weiner use the term *community-integrated GIS* to describe their work with local communities in South Africa to examine and transform postapartheid land reform policies. The authors acknowledge that GIS remains an “expert system” and cannot be under the control of community members, who do not have the capacity to direct the research themselves. Nonetheless, their community-based research methods explicitly focus on democratizing participation, broadening access to spatial data, incorporating local knowledge, and surfacing (rather than suppressing) the conflict inherent in spatial decision-making practice. In other words, to the extent possible, GIS is not used to impose a particular spatial framework that structures how reality can be represented. Rather, it is used as a way to juxtapose multiple and potentially conflicting realities that reflect the socially differentiated perspectives of participants.

Scholars and practitioners have developed several specific methods that can be used to facilitate PGIS research. These include participatory 3D (three-dimensional) modeling, photo mapping, sketch mapping, and resource mapping. In general, these methods are designed to enable low-cost and inclusive participation for community members who may not have computer literacy or access. Such methods also allow for the flexibility to incorporate unconventional forms of local spatial knowledge and storytelling. However, one criticism of these methods, and of participatory GIS more generally, is that they tend to rely on conventional GIS software and have done little to advance the technology in ways that address fundamental limitations in data structure and system design.

Collaborative Decision Support GIS

A second approach to PPGIS finds its roots in research into spatial decision support systems (SDSS). SDSS scholars have long promoted the utility of information technology and GIS for structuring complex spatial problems to aid decision makers in identifying optimal solutions. These systems have been applied to problems such as water resource management, locating public facilities, and land use planning. In many cases, SDSS rely on problem-structuring methodologies such as multicriteria analysis or agent-based modeling, which require predefining many important aspects of the problem to make the process of identifying a solution more tractable. In recent years, scholars have begun adopting SDSS concepts and methodologies to develop new GIS applications designed to support collaborative group decision making under the rubric of “participatory GIScience” (geographic information science) and “collaborative GIS.” These systems often enable sophisticated analytical capabilities that far exceed those found in most PGIS methods. However, these systems also tend to predefine the problem in question in advance of any collaborative process as a necessity for data gathering, system design, and software development. As a result, collaborative SDSS approaches lack the flexibility that PGIS methods have for incorporating different problem understandings and local knowledge.

Unlike PGIS, collaborative decision support approaches to PPGIS assume a clean distinction

between the problem space (i.e., the criteria under consideration) and the decision environment (i.e., the social and political context). These approaches also tend to assume a homogeneous group of participants who all understand the problem in approximately the same way but who may value the solution criteria differently. PGIS approaches do not make this assumption, and they often enable participants to construct their own spatial representations of problems, which may be very different from those preconceived by the researchers or system designers. These distinctions point to a fundamental tension and trade-off at the heart of any effort to support collaboration with GIS—between enabling analytical problem solving activity and enabling the exploration of diverse problem understandings.

Web-Based Grassroots GIS

A third approach to PPGIS is still in its early stages of fruition. Recent advances in “Web 2.0” technologies have enabled the creation of sophisticated Web-mapping applications, which are freely available to anyone with an Internet connection, a Web browser, and basic surfing skills. Notable among these are Google Maps and, more important, the thousands of “mashups” created using the Google Maps application programming interface (API). Mashups are Web applications that combine disparate sources of data and functionality. For example, the Web site ChicagoCrime.org displays crime data published by the Chicago Police Department using the Google Maps interface. The result is easy and widespread public access to an important data resource previously unavailable to all but the most extremely determined. Christopher Miller describes a harbinger of the next stage in the evolution of Web mapping mashups—a Web site that enabled New Orleans residents affected by Hurricane Katrina and its aftermath to share spatially referenced text messages on a Google Map interface. Miller argues that this simple application—developed by two college students in Texas in the days after the storm hit—was able to facilitate essential communication needs among residents that were unfulfilled by the massive federal disaster response efforts. Since then, there has been a proliferation of Web applications that enable anybody to publicly post and

share their own spatial data and georeferenced local knowledge, including WikiMapia, OpenStreetMap, Google Earth, and Google Maps. Additionally, the advent of “geotagging” in blogs and photo-sharing Web sites allows people to simply add geographic metadata to information they’re already posting online.

PPGIS scholars and practitioners are only beginning to consider the implications of Web services and applications such as these, which decentralize the control and dissemination of geographic data while facilitating a flood of new “volunteered” geographic data into the public domain. While some point to the highly structured and top-down model of “citizen science” (e.g., the Christmas Bird Count) as a precursor, Web mapping applications—particularly of the mashup variety—often facilitate less predictable flows of spatial information that reflects the disparate perspectives and subjectivities of the creators themselves. In other words, we may be witnessing the emergence of a “grassroots” PPGIS no longer dependent on the assistance of planners or university researchers. This approach is epitomized in thematic projects such as GhostBikes.org, which collects local knowledge from readers about locations where bicycle riders have been hit or killed by cars. The locations are both mapped online and memorialized by a white junker bike placed at the location of the incident. Projects such as this raise public awareness of socially significant spatial stories. By shaping the meanings ascribed to public space, these projects have the potential to empower communities in debates over how to manage and develop that space.

Each of these approaches addresses the concerns regarding the social implications of GIS in different ways. Yet all three of the concerns are still relevant today. Despite the advances in Web-based grassroots GIS, the wide disparities in access, expertise, and resources still shape who can construct, display, and disseminate spatial data online—much less advocate effectively for social change. While multimedia capabilities now enable the representation of some new kinds of local spatial knowledge, broader institutional and political structures still privilege some forms of spatial knowledge over others in decision processes. Although mashups have enabled the (social) construction of Web mapping applications by anybody with basic

programming skills, almost all rely on a single mapping interface designed by a corporation (Google) fundamentally concerned with the potential for boosting advertising revenues, not democratizing spatial decision making. In other words, GIS is (and will always be) a simultaneously empowering and disempowering technology. Each approach to enhancing public participation in governance (or mapping more generally) creates some new opportunities while foreclosing others. This explains why a great deal of PPGIS scholarship is in the form of case studies, which report on the social, political, and economic complexities that shape the form and effectiveness of PPGIS endeavors. As the field of PPGIS matures, researchers and practitioners are beginning to revisit previously underexamined assumptions about what it means to “empower” participants and what forms of “democracy” we should endeavor to bring about. Such questions are vital in an era of neoliberal governance reforms that often seek devolution of political authority and increased community involvement in spatial decisions while at the same time privileging market forces and economic growth. In other words, PPGIS is necessarily a *political* project in which public participation works to challenge or solidify established forms of spatial governance.

PUBLIC POLICY, GEOGRAPHY OF

The geography of public policy concerns spatial and human-environmental aspects of the origin, formulation, implementation, monitoring, and evaluation of public policy. Many American geographers have made important contributions to domestic public policy, including Henry Gannett on census geography in the late 19th century, Gilbert White on water issues in the mid 20th century, and Brian Berry on metropolitan issues in the late 20th century. Other American geographers have made important contributions to American foreign policy, including Isaiah Bowman, who served as America's Chief Territorial Specialist during the Versailles Treaty negotiations at the end of World War I; Lewis Alexander, who contributed to U.N. Law of the Sea negotiations in the mid 20th century; and George Demko, who dealt with international humanitarian and boundary issues as Director of the Office of Geographer in the U.S. Department of State in the late 20th century. This entry describes the field of public policy geography and the function of public policy in American life, both as a source of employment and, more broadly, as a dimension of the collective life of citizens. It then examines the models that have been used in research on public policy, along with the settings in which it occurs and the various ways in which it is manifested. One area of particular interest to geographers is the expanded role of public sector employment related to geographic information systems (GIS) and remote sensing.

Definition of Public Policy Geography

Rather than as a subdiscipline of geography, such as biogeography, economic geography, or political geography, *public policy geography* is perhaps more appropriately regarded as an approach that crosscuts subdisciplinary boundaries to engage problem-oriented research in both human and physical geography. Public policy geography can be thought of as a spatial and environmental approach to interdisciplinary public policy analysis. The methodology of public policy analysis draws from

and integrates elements from many disciplines, including economics, geography, law, political science, and sociology, as well as agronomy, cartography, demography, ecology, international affairs, mathematics, military science, operations research, public health, remote sensing, and statistics. Public policy geography thus contributes to a wide interdisciplinary realm of investigation, but with special attention to the spatial and human-environmental aspects of public policy analysis.

It is pertinent to note that the etymological origins of the word *policy* show derivation from the Sanskrit *pur*, or “city,” and the Greek *polis*, or “city-state,” which evolved into the Latin *politica*, or “state,” and later into the Middle English word *policie*, which referred to the administration of the state or the conduct of public affairs. The modern words *policy*, *politics*, and *police* thus share related origins, all of which reflect the polity as that specialized sector of society whose rules, regulations, and laws can be imposed on all affected citizens, whether willingly or not. The Latin word *populus*, or “people,” evolved into the Middle English *publique*, for “all the people,” and later into *public*, meaning “relating to or affecting all the people.” And *geography* is derived from the Greek word *geographia*, or “Earth description.” So *public policy geography* links Earth description with politics and government activities as well as with the direct or indirect interests of all the people within a society or community.

Public Sector Employment

While all people are at least potentially affected by public policy, those actually engaged in public policy decision making or implementation are the most directly involved. Using aggregate local, state, and federal government employment for 2005 as a rough indicator, about 24 million Americans, or about 8% of all U.S. residents, have some sort of formal responsibility for legislating, administering, enforcing, adjudicating, conducting, or defending public policy within the United States. Public sector employment included 13.9 million local government workers, 5.1 million state government workers, 2.7 million federal domestic workers, and 2.2 million federal defense workers. Although many public employees are

more responsible for implementing than for formulating public policies, including public school teachers, zoning administrators, park rangers, air traffic controllers, the local police, public health workers, and welfare workers, they nevertheless constitute one of the largest pressure groups in the United States. It is a fact, for example, that there are more primary and secondary school teachers (about 3.4 million) than farm operators and farm workers (about 3.3 million) in the United States, so that the National Education Association potentially could mobilize a larger lobbying effort than the American Farm Bureau.

Public Policy and Collective Existence

While only about 1 in 12 Americans actually works at a government job, all Americans have a varying degree of interest in each and every matter of public policy, either as taxpayers or as citizens. The urge to keep the private sphere of collective existence as large as possible, based on the Jeffersonian principle that “that government is best which governs least,” persists as a foundational tenet of American political ideology. But the public sector has expanded enormously, so that by early in the 21st century, in 2005, nearly one third, or 31.3%, of the U.S. gross domestic product (GDP) was appropriated through government budgetary processes. Federal outlays alone constituted 20.2% of GDP, including grants to state and local governments, which were about 3.5% of GDP; state and local outlays from their own revenue sources constituted another 11.1% of GDP. Many Americans receive direct pecuniary benefits from government in the form of retirement income, unemployment support, medical assistance, or other transfer payments, which now constitute nearly half of all federal outlays as well as a significant fraction of state and local government expenditures.

Direct financial dealings with governments in the form of taxes paid or expenditures received are only one facet, albeit a very important one, of each citizen’s overall stake in public policy. For example, most Americans are born in public hospitals, educated in public schools and colleges, drive vehicles on public roads, drink water from public water supplies, flush waste down public sewers, send trash to public landfills, and so on.

Figure 1 A schematic drawing of the public policy system. Public policy is a complex, contested outcome reflecting the local socioeconomic environment, state imperatives, and the interests and powers of multiple stakeholders.

Source: Author, compiled from multiple sources.

And the places where they work are zoned for commercial, industrial, or institutional uses; regulated by various worker protections; powered by public utilities; linked to other places of work by public highways, maritime terminals, or airports; and so on. In short, matters of public policy permeate virtually every imaginable aspect of collective existence in a modern society, so much so that any investigation of public policy inputs, processes, or outcomes tends to be very difficult to circumscribe in a suitable manner.

Conceptual Frameworks

Complexity is a recurrent theme in books on public policy analysis. Modeling strategies can help focus on the most salient aspects of public policy issues, but even the potential range of modeling frameworks that have been applied in public policy research is quite broad. These include institutional models, group models, elite models, incremental decision-making models, game theoretic models, public choice models, systems models, as well as

others. Some public policy models have been expressed as sets of verbal axioms or inferences, while others have been formalized in complex mathematical or complex statistical terms. A very simplified graphical model can be used to illustrate some of the most commonly recognized components of a public policy system (Figure 1). Policy stakeholders and institutions include the people or groups likely to be directly or indirectly affected and the public as well as private bodies likely to be directly or indirectly involved in influencing or determining public policies. Examples of possible stakeholders include property owners, citizens' groups, workers, environmental activists, farmers, students, teachers, or any other identifiable set of interested parties who could be affected. Examples of policy-relevant institutions include federal, state, or local legislatures; executives, agency heads, justices, judges, and other officials on the public side; and labor unions, business groups, professional organizations, churches, nongovernmental organizations (NGOs), and other entities on the private side. Although legislatures, and sometimes courts,

may make the final determination, the impetus for and perhaps even the specific wording of part or most of a bill or ruling is apt to be traceable to an earlier administration's "white paper" or to a private "model statute."

The Policy Environment

Social, economic, and environmental conditions constitute what political scientists or policy analysts are likely to call the "policy environment." Policy-relevant problems can arise in any sector of collective existence and are likely to manifest subjective as well as objective properties. Objective properties are the observable and measurable features of a circumstance, such as income distribution, acres cultivated, or ethnic residential separation. Subjective properties reflect the values and interpretations of interested parties, who may be in considerable disagreement with one another. For example, different parties might well express differences over issues such as the specification of a poverty threshold, an agricultural zoning criterion, or a housing discrimination indicator. Indeed, there is in American society, as in most other societies, a general reluctance to address any other than the most compelling "demands" for collective action, so that massive "mobilization" efforts through advertising, lobbying, and other "pressure group" activities are likely to be needed to put a particular social, economic, or environmental issue on the public agenda, and each effort to do so is apt to be challenged by individuals or groups likely to prefer the "status quo" over any possible changes. As just one indicator of the contentiousness of the public agenda-setting process, hundreds of millions of dollars are contributed to and spent by primary and general election campaign organizations in the process of electing a president of the United States; and many more hundreds of millions of dollars are contributed to and spent by office seekers at other levels of American governance.

Public Policy Outputs

Public policies and public services include the laws, regulations, programs, services, and other relevant public policy instruments that emerge as

outputs from the public policy system. These outputs can be expected to generate or alter the incidences of benefits/costs that are enjoyed/borne by various groups of people in various geographical settings. Different policy categories, such as educational services, defense procurement, welfare assistance, criminal justice, drought or flood prevention or mitigation, and so on, are apt to show geographically distinctive patterns of impact, depending on the social and environmental conditions, stakeholder mobilization and influence, decision makers' policy priorities, and so on. Issues of confidentiality, national security, benefit spillovers, data collection costs, and other problems can make geographical impacts very difficult to ascertain for some policy categories, such as for various types of defense or national security policy, business or financial sector regulation, environmental hazard mitigation, or the direct and indirect regional impacts of foreign trade imbalances, to list just a few examples.

The likely validity of an a priori expectation of geographical variability can be illustrated by considering the state-level distribution of U.S. federal expenditures for Fiscal Year 2005 (Figure 2). In terms of function, the Department of Health and Human Services (26%) and the Social Security Administration (24%) together account for about half of all federal outlays. Next in line are the Department of Defense (17%) and the Veterans Administration (3%), which together account for about one fifth of all federal spending. The remaining third includes all other federal agencies, with the Department of Agriculture (4%) and the Postal Service (3%) having appreciable shares. While retirement, disability, and other direct payments may tend to equalize federal outlays in relation to population distribution, federal wages and salaries, procurement contracts, and some grant programs may tend to have much more geographically concentrated impacts, with the result that the overall pattern is one of considerable geographical complexity. States with well below average levels of federal outlays per capita are found in New England, the Midwest, and the West, but so too are states with well above average levels of federal outlays per capita. Large agricultural assistance payments in low-density states help explain the high levels in the northern Great Plains, while defense and other federal

Figure 2 U.S. federal government outlays per capita, 2005. Federal government expenditures per person are, ironically, often highest in small, lightly populated states that often view federal authority with suspicion

Source: Data from the U.S. Bureau of the Census. (2007, September). *Consolidated federal funds report for fiscal year 2005* (p. 21). Washington, DC: Government Printing Office.

activities help explain the high levels in several states adjacent to the nation's capital or along the Atlantic and Caribbean coasts. But the overriding impression is one of geographical complexity, with few unexceptional trends being apparent. The complexity theme so often encountered in public policy analysis literature is thus reinforced by examining the overall state-level geography of federal government activity in the United States.

Public Policy and GIS

One area of rapid expansion in public policy related to geographical research and public sector

employment of persons with geographical training involves the mapping sciences of cartography, GIS, and remote sensing. At state and local levels of public sector employment, many geographers with mapping science skills can be found working in planning, natural resources, transportation, utilities, economic growth, health services delivery, and many other areas in which computer-produced maps and other forms of geographic analysis can help inform public policy making or evaluation. At the federal level, geographers with mapping science skills can be found in many agencies, including the departments of Commerce, Defense, Health and Human Services,

Homeland Security, Housing and Urban Development, the Interior, State, and Transportation. And, of course, much of the impetus for and financing of important modern advances in GIS and remote sensing have directly come from the federal government. Although military and international security applications have prompted many advances in GIS, remote sensing, and global positioning systems (GPS), domestic applications have also played an important role. For example, much of the pioneering work in developing topological data structures, which are now essential to many domestic and commercial applications of GIS, was undertaken by geographers in the Geography Division of the U.S. Bureau of the Census, in developing the DIME system for the 1970 Census and the TIGER system for the 1990 Census. Early-21st-century pizza delivery, emergency vehicle routing, school attendance districting, and, of course, electoral gerrymandering would be much less efficient without TIGER-powered GIS!

PUBLIC-PRIVATE PARTNERSHIPS

Public-private partnerships (PPPs) are contracts or formalized relationships between a public sector institution and a private sector institution, usually relating to the provision of public services or infrastructure. All PPPs involve the transfer of risk between the parties, through the transfer of ownership, control, financing, or operation of the service. In contrast to wholesale privatization, the responsibility for a PPP is shared between the private and the public sectors and regulated by the latter.

There are significant national variations in the definition and practices of these partnerships, and their levels of formalization range from simple commercial contracts to the establishment of autonomous organizations with various degrees of authority. Countries as diverse as Canada, Ireland, and South Africa have set up governmental PPP units. Particular PPP policies and models, such as the Public Finance Initiative in the United Kingdom and the build-operate-transfer model, which is well established in Australia and Asia, have gained popularity among policymakers and have consequently been imported and adapted by other states. Leading international financial institutions and development agencies, such as the United Nations and the World Bank, have shown strong support for PPPs as a strategy for development and poverty reduction, and the private sector is now a dominant actor in public service delivery in many developing countries.

PPPs are, like privatization, subject to political contestation. Proponents of this model often claim that PPPs can bring in finances and resources otherwise unavailable to the public sector. It is also argued that PPPs represent "value for money," as private sector business principles are more efficient and because PPP involves the transfer of risk to a private contractor. In contrast, opponents see the profit motive as unsuitable for the realm of public services, which is seen as constituted by the notion of public need. It is held that private contractors can only make a profit on public services through wage and benefit cuts and the introduction of

cost recovery as a pricing principle. Another criticism that has been raised is the effect of PPPs on public accountability and their perceived lack of democratic input. While proponents include “third-way” governments, business interests, and conservative political parties, the opposition to PPPs is often spearheaded by trade unions, social movements, and leftwing political organizations.

In the critical human geography tradition, PPPs are seen as important components of neoliberalism and in the historical evolution of this paradigm. It is argued that the privatization programs and competitive tendering schemes that were initiated by Anglo-American governments in the 1980s were increasingly faced with their own socioeconomic contradictions. Neoliberal regimes were looking for ways to increase market involvement in public services without surrendering control over the politics of reproduction. PPP models and new, sophisticated models of regulation emerged as a response to the lack of coordination that characterized this early neoliberalism. Gaining popularity throughout the 1990s, these partnerships blurred the distinction between the private and the public sectors in many countries. These new forms of state control and intervention combined with increased private sector involvement is often termed *neoliberal governance*. There are also scalar dynamics to these processes, as the PPP approach, accompanied by a discourse of decentralization, has become prominent in local authorities in the United Kingdom and elsewhere.

PUBLIC SPACE

Many different meanings come to mind when one thinks of public space. Most definitions of public space involve what are usually thought of as communal “civic” spaces, such as public squares, city parks, public streets, sidewalks, and plazas. These spaces represent the stage on which communal life unfolds and where the ebb and flow of human exchange takes place. In this vein, public spaces are communal spaces where social, political, and economic activities take place. Other definitions of public space include those public domains that go beyond the local scale and that affect everyday communal life, such as global institutions or even the “spacelessness” of the Internet.

Public space is a necessary element of human existence, providing channels for movement, nodes for communication, and common areas for play and recreation. Access to public space helps people satisfy everyday needs, exercise significant aspects of human rights, and protect special cultural meanings. Government buildings, such as public libraries and many other similar buildings, are also public spaces. But not all state-owned buildings fall under definitions of public space. Some spaces are “semipublic,” where the right to occupy public space is restricted based on certain economic restrictions. Entry to public parks can also be restricted based on the ability to pay a fee or based on a user’s residence. Some privately owned spaces, such as cafes, are sometimes thought of as public spaces, but they are public only to the extent that one has money to spend. Shopping malls are public in the sense that everyone has legal access, but private controls over speech and behavior frequently apply.

What we normally think of as public space today stretches back to premodern concepts of the public marketplace in Mesopotamian cities and in ancient Greece and Rome. Sometimes called the *agora*, these were sites of great importance, serving as places for formal and informal communication and economic exchange. In later years, these open marketplaces incorporated open spaces for political assembly, sports, and religious gatherings. Public spaces as sites for economic, cultural, political, and social activities are still very much a vital part of communal life in many parts of the

San Marco Square and Palazzo Ducale, Venice

Source: Morguefile.

world today. Various cultures place different emphases on the value of public space. For example, Latin American cultures place great emphasis on displays of wealth and religious power in palaces, town halls, and churches that face the main street and public squares. Yet in the Muslim world, there is limited public space, apart from public markets and shopping centers. Instead, private spaces such as the home, the mosque, and religious schools are rich in architectural design and cultural expression, and it is here that much of communal life resides. Hence, the idea of a public-private balance is unique to each culture.

Beginning in the 18th century, universal access to public space was an important aspect of democratizing societies. But in practice, public access was anything but universal. Public space was

restricted by economic class, race, ethnicity, and gender, existing alongside class exploitation, slavery, and the oppression of women. In other words, universal access to public space is never guaranteed, never universal, and always a struggle. Feminist geographers have argued that notions of public space serve to spatially entrap women in terms of the built environment. Public spaces of the city, for example, are coded as masculine spaces—that is, the places of productive work accomplished primarily by male breadwinners. The suburbs represent private, feminine spaces, which are places of nonwage domesticity where reproductive work and child care are relegated primarily to women.

In recent decades, geographers have begun to examine how the nature of public space as a space

of everyday encounters is at risk, an increasingly problematic issue considering the rapidly diversifying urban populations in many places throughout the world. Indeed, public spaces are being privatized at an alarming rate, isolating people and diminishing the kinds of social networking inherent in public space. Neoliberal economic policies, along with technologies that place less emphasis on face-to-face personal communication, have only served to exacerbate the problem. Increasingly, public space is placed under tighter surveillance to improve security, mostly in the name of fighting the “War on Terrorism.” These current struggles have everything to do with contemporary debates that affect the nature of social relationships within the realm of public space, particularly for those on the margins of society, who have little power and influence. Indeed, the basic rights that reinforce any coherent sense of the public sphere are still very much constrained by the geographies of race, class, and national origin. In a world increasingly defined by private property and security fears (whether real or perceived), public spaces as spaces for human interaction and communal life are still very much tied in with dimensions of social difference and struggles for inclusiveness.

Many speculate that the nature of public space has not diminished but has been transformed by developments in communications technology. They maintain that the electronic spaces of the media and computer networks have opened up a new frontier of public space in which the material public spaces of the city are now superseded by the forums of television, cell phones, and the Internet. For many scholars, modern communications technology is now the primary site for public activity in general and politics in particular. But the question remains as to what this means when being part of “the public” no longer requires being *in* the public but instead can be accomplished in a private home by switching on the television or logging on to the Internet.

Approaches to public space involve balancing the public and private spheres by examining the ways in which contemporary public space is fragmented, both in a physical and in a metaphorical sense. Access to public space is about human relationships and the subsequent power struggles for recognition that result from social, cultural, economic, and political inequality. In a physical

sense, public space is about how these inequalities work through visual cues, such as barriers or boundaries. How people conceptualize these various definitions of public space is vital to how—and where—they grapple for legitimacy from the state or the community. Powerful institutions such as the state have their own ways of conceptualizing public space. Understanding these differences is vital for those who wish to contribute to particular visions of the term *public space* and its implications for creating a more just world.

PUBLIC WATER SERVICES

Public water services encompass the provision of collective services to a given community, typically an urban center. Water supply entails the abstraction of raw water from a natural source, such as surface water (e.g., rivers and lakes) or groundwater (i.e., aquifers); its treatment to make it fit for human consumption; and, finally, its distribution to households and commercial users via an underground pipeline network. This entry discusses public water services as a natural monopoly, the history of public water service organizations in Organisation for Economic Co-operation and Development (OECD) countries, public water services in developing countries, global trends concerning the

public versus private provision of water services, the restructuring of public water operations, and the principles underlying successful public sector reform.

A Natural Monopoly

The technical characteristics of water supply and sanitation services affect their organization and regulation. Because, at current technology levels, it is excessively expensive to set up more than one pipeline network to allow more operators to compete with each other, water supply is regarded as a typical natural monopoly. This implies that only one operator, whether public or private, is allowed to operate in a given operation area (e.g., in a municipality). If the water supply operator is a public undertaking, it is often appointed without competition for an unlimited duration and is subject to the scrutiny of public authorities. In recent years, the international practice in case of appointment of a private company as water supply operator is that this is subject to competition for the market, in the form of competitive bidding whereby the successful bidder enters into a long-term contract (typically up to 30 years).

Regulation is intended to be a substitute for or at least a complement of competition, whose introduction in the water sector is limited. Throughout the duration of the contract, the private operator is often subject to the scrutiny of local authorities or regulation by a specialized agency to try to prevent it from abusing its monopolistic position at the expense of consumers and the environment (e.g., by overcharging consumers or underinvesting in the system). If the introduction of competition is limited due to the technical characteristics of the sector, regulation is also problematic due to the asymmetry of information between the regulator and the regulated undertaking. In fact, the operator usually knows more about the state of the system and the conduct of operations than the regulatory agency, and it is thus able to exploit this advantage to pursue its interests (e.g., profit maximization in the case of a private operator) to the detriment of consumers, the environment, or the local community. It is thus important to identify governance mechanisms that will result in aligning the interests of the operator with those of the community.

Public Water Service Organization in OECD Countries

In Europe, urban water systems began developing in the 17th or 18th centuries as a limited service to affluent customers and as a public assistance for fire control. As cities grew in the 19th and 20th centuries, the demand for water consumption grew, and public health issues became more acute. While the initial systems were usually started by private companies, during the 19th century, the utilities were fairly soon taken over by municipalities in nearly all European countries.

There were a common set of reasons for this, ranging from the limited capacity of private operators to extend public water services to the urban population to the need to avoid the excessively high costs of private sector provision. In addition, municipal governments gained the right to borrow money to cost-effectively invest in the development of their own systems. The extension of water systems in European cities thus almost entirely took place under public operators and thanks to public finance.

The same process occurred in the United States. By 1897, 82% of the largest cities were served by municipal operations. At the end of the 20th century, the proportion was broadly the same and was not expected to change significantly.

Today, France and the United Kingdom are the only two OECD countries whose water operations are mostly run by private companies. However, even in these two cases, universal coverage was achieved only through the predominant role of public operators and public finance. Historically, private operations, market forces, and competition have not been central to attaining vital social objectives.

Developing Countries, Independence, and the Colonial Legacy

The development of water supply as a universal public service in developing countries has a different history. In the colonial period, while Europeans were extending public networks in European cities, in the colonies, water supply was focused on the colonial elite, and the systems failed to provide for the general population. This colonial development left a physical legacy of chaotic and

incomplete networks in cities under colonial control, such as Baghdad, Bombay (now Mumbai), and Lagos. In Kampala, Uganda, the British colonial power's insistence on cost recovery through tariffs meant that access to the service was unaffordable for ordinary Africans.

Colonial rule also left a socioeconomic legacy of more unequal societies, which makes today's problems more acute. In Africa, the colonial legacy of water systems designed to serve primarily the urban elites was exacerbated following independence by the decline in the terms of trade of the principal outputs and exports, which took place in the 1970s. This resulted in the decline in government funding of the capital expenditure necessary to extend service coverage and a general worsening of the national economy.

The failure to achieve universal coverage in developing countries can thus be explained by a combination of factors, including fragile institutions, unequal societies, inadequate public finances, and deteriorating economic conditions.

Recent Trends: History Repeating?

It is estimated that, to date, more than 90% of public water services worldwide are provided by public operators. Public sector predominance in the operation of public water services remains even after almost two decades of the so-called Washington Consensus, favoring market-based solutions and private sector participation. Supported by international financial institutions and bilateral agencies, water multinationals expanded considerably from the 1980s to the end of the 1990s. However, the fortunes of international water supply companies have collapsed dramatically in recent years, due to their failure to make adequate profits in developing countries. Since 2003, the multinational companies have halted and reversed their expansion. One key reason for this is that the developing countries could not support the rate of return required by international equity capital.

The failure to achieve an adequate return on capital is partly due to the remarkable amount of public campaigning against water privatization, a global phenomenon. The uprising that led to the termination of the private water contract in Cochabamba (Bolivia) in 2000 was the first and most dramatic of a series of reversals. The collapse of the

Argentinean economy led to the ending of water concessions in Buenos Aires and Santa Fe. In Africa, contracts were terminated in Gambia, Mali, Chad, Nkonkobe (South Africa), and Dar es Salaam (Tanzania). Privatization has faced similar rejections and reversals in developed countries, too: for example, in Atlanta and Grenoble (France).

Contrary to theoretical expectations, the private companies failed to show greater efficiency than public sector operations. A growing body of empirical evidence from all continents shows that ownership does not appear to make any significant difference to efficiency.

This can be explained by the problems observed under private water operations in developed as well as developing countries, which range from corruption, aiming to secure access to the local market and capture local decision makers and regulators, to a variety of rent-seeking practices that resulted in inflated pricing. These include the manipulation of tariff formulas, the systematic renegotiation of prices upward and postponement or downward revision of investment commitments, and overestimation of required investments. Furthermore, private water operators might resort to transfer pricing across vertically and horizontally integrated transactions. This takes place through privileged access to subcontracting or payment to the mother company for the purchase of costly managerial expertise and technical assistance.

Restructuring of Public Water Operations

Despite the widespread belief that public operators are inherently inefficient, there are many examples of effective public sector water services in developing countries, based on various criteria. These cases can be observed in all continents, not just in affluent countries. These are not acknowledged as often or as loudly as they should be, partly because the recent emphasis on private sector activity has obscured the achievements by the public sector. As the limitations of the Washington Consensus become more apparent, the attainment of social and developmental objectives will largely depend on strengthening and scaling up positive public sector experiences. Empirical evidence suggests that, once the different context is considered, the principles underlying successful reform of public

water operations might equally apply to developed as well as developing countries.

Principles of Successful Public Sector Reform

Unlike private companies, which see profit maximization as their overarching goal, public water operators have no single set of objectives. In principle, public sector undertakings pursue a plurality of objectives to promote the public interest from an economic, social, and environmental point of view. In practice, due to the monopolistic nature of water service provision, the success of public water operations in achieving the intended objectives relies on the effectiveness of accountability mechanisms.

Public water operations appear more suitable than private ones to contemporarily address a variety of public interests and sustainability objectives at the political and institutional, economic, social, and technical and environmental levels. When this happens, economic objectives are not prioritized over social and environmental goals but are seen as instrumental to fostering the sustainability of service provision. This is not a necessary outcome of public water operations but requires the introduction of accountability and transparency mechanisms such as advanced forms of democratization and public participation so that the management and local authorities can be made responsible to civil society for their decision and conduct. Though the introduction of advanced participatory mechanisms is not associated with all public operations, they are never to be found under private operations. The reason for this is that because private companies have an imperative to maximize profit, they cannot accept “intrusion” from stakeholders such as consumers’ representatives and pretend to exert absolute control over the management of operations.

The predominance of public water operations at the global level, historically and today, is a sign of the difficulties of achieving the intended development and sustainability objectives under private operations. This state of affairs is likely to continue in the future, as long as the technical characteristics of the service remain fundamentally the same. The fact that successful public sector reform is possible suggests that public sector

predominance should be seen as an opportunity in the pursuit of the Millennium Development Goals rather than as a hindrance. The efforts of international financial institutions and governments should be directed at making public water operators accountable and effective service providers through in-house restructuring under public ownership and management. When local capacity is the problem, this can be addressed by cooperation among public sector entities, as is the case under public-public partnerships.

Finally, institutional strengthening and capacity building should be pursued in parallel to efforts to sustainably finance the expansion and maintenance of infrastructure. This requires renewed attention to the potential of public finance and public subsidies based on (progressive) general taxation as a cost-effective and equitable financial instrument.

PYROGEOGRAPHY

Fire puts asunder what photosynthesis hath joined together. The alchemy of fire can be described physically as a biochemical reaction requiring the simultaneous presence of fuel, heat, and oxygen. Pyrogeography is a multidimensional subfield of geography concerned with the study of the complex space-time interactions between fire and people. Humans have always been the keepers of the flame; thus, pyrogeography is, true to its geographic roots, integrative—spanning the physical, biological, and social sciences. It is an exemplary coupling of natural and human systems.

The fireshed—the pyrogeography equivalent of the watershed—consists of four variables: fuel, weather, topography, and people. *Fuel* refers to combustible biomass. *Weather* describes precipitation, temperature, and relative humidity variations that control ignition probability. *Topography* determines the position of fuels on the fireshed. This aspect controls a fuel's productivity and curing via intercepted solar radiation, moisture, and the flows of wind; slope steepness mediates fire spread via effects of radiative and convective heating. *People* affect and are affected by fire, extending fire's reach beyond the biophysical environment into the human realms of culture, politics, and economics.

Origins

Before humans, climate determined the general fire patterns in accord with climate-soil-vegetation relationships. Precipitation produced fine grass fuels. Seasonal lightning propagated fire from grassy lowlands into forested uplands and vice versa. Fire recycled nutrients and thus promoted

Surface fire reduces ground fuels, recycles nutrients, and maintains open, healthy conditions.

Source: U.S. Forest Service.

biodiversity. It was by this process that fire renewed the landscape (see surface fire photo).

Processes

Fire is a keystone ecological process, standing among the few natural phenomena humans can control. Pyrogeography seeks to clarify the evolutionary importance of fire and human culture. Before humans, fire was ignited primarily by lightning and occasionally by geological actions (e.g., volcanism and rock falls). Today, many wildfires are started by people. Combustion potential is controlled by vegetative fuel moistures: Live fuel moistures respond seasonally to broadscale interannual variations in precipitation, whereas dead fuel moistures can respond hourly to local meteorological conditions (e.g., relative humidity, wind).

(A) Bright areas represent high live-fuel moisture stress, thus an elevated fire potential. Southwestern North America shows particularly high stress in June. (B) The arrival of monsoonal rains in summer eases live-fuel moisture stress across southwestern North America by September.

Source: Yool, S. R. (2004). Wildfires. In J. Stoltman, J. Lidstone, & L. M. DeChano (Eds.), *International perspectives on natural disasters* (chap. 5, pp. 107–130). London: Kluwer.

Fuels are both a source and a sink for atmospheric carbon: Emissions from biomass burning are sources of particulates and carbon dioxide (CO_2) that affect Earth's radiant energy budget and atmospheric chemistry, influencing climate on regional and global scales. Live fuels harvest atmospheric CO_2 and thus complement Earth's oceans as terrestrial sinks for planetary carbon. Fire scars in tree rings and charcoal in

sedimentary deposits record terrestrial carbon exchanges through deep time, showing the close coupling between climate, fire, and vegetation. Modern fire atlases from ground observations and satellites show increased fire activity in many regions. Complex combinations of climate warming and drying, land use change, and the spread of pyrogenic invasive plant species likely explain these recent changes.

Technologies

Geospatial mapping technologies, powered by the human intellect, can coax complex pyrogeography from raw data. Maps showing the global distribution of fire serve to inform questions of how climate-fire interactions explain contemporary and predict future Earth surface patterns. Such maps can be used by ecologists interested in fire regimes, by Earth systems scientists monitoring fire-related carbon fluxes to the atmosphere, by historians and economists describing the culture and risk of fire, and by geographers investigating space-time variations in fire hazards. Pyrogeographers studying wildfire hazards, for example, use maps as their principal medium of communication. Geospatial technologies, including remote sensing and geographic information systems (GIS), facilitate mapping and modeling of wildfire hazards and effects from local to global scales. Remote sensing technologies include airborne and spaceborne remote sensing systems to determine prefire fuel moistures (see southwestern North America photos), active fire spread (see ASTER photo), and postfire severity and resilience (see Landsat photo). (Resiliency is the response to severity: the ability of a fireshed to recover after a fire.) GIS technology unifies these

fire-related data, enabling predictive modeling and facilitating fire management.

Integrations

Geospatial information technology allows integration of natural and cultural data into wildfire management alternatives. A first-generation Fire-Climate-Society model (FCS-1) is a GIS that integrates geospatial information and user preferences (Figure 1). Composite wildfire hazard maps depict priority areas for management activities, including prescribed burning or mechanical thinning.

The FCS-1 model translates user preferences into fire hazard maps via the Analytic Hierarchy Process (AHP). The AHP enables complex decisions involving data that are difficult to quantify. Stakeholders are presented all unique pairwise

combinations of the nine primary data layers. Each stakeholder produces a relative weighting for each unique pair. AHP derives from this set of pairwise comparisons a weight for each primary data layer. Weights are multiplied by actual data values. The sum of these products produces a custom composite priorities map that exemplifies pyrogeography in practice (Figure 2).

QUALITATIVE METHODS

Qualitative methods can be characterized by their concentration on subjective experiences and the subjective dimensions of the social. These methods are labeled as qualitative because their aim is to investigate deeply into each single case rather than produce a more abstract and concentrated set of quantitative data. Even if the results gained with the help of qualitative methods are not, in general, statistically representative, their outcomes and interpretations are somewhat more than the descriptions of individual cases. Because each single case is considered as being a part of society, reflecting wider processes, qualitative research produces results that can be generalized. Today, qualitative methods are in common use in the social sciences, including human geography. Qualitative methods are used sometimes in combination with quantitative methods. After identifying a problem with a quantitative approach, it may be further investigated with qualitative research (and vice versa). This entry describes the development of qualitative methods in geography, examines the main characteristics of such research, and reviews the methods used to gather and analyze data.

The Development of Qualitative Methods

The main theoretical and practical development of qualitative methods was carried out in sociology and anthropology. Geographers adapted these

insights to and enhanced them in their own research. Anthropologists such as Bronislaw Malinowski and Franz Boas pioneered the use of qualitative methods with observations in ethnographic field studies at the start of the 20th century. In the 1920s, members of the Chicago School of sociology and urban geography, such as Robert Ezra Park and Ernst Burgess, applied—in addition to some quantitative methods—mainly qualitative methods, such as participant observations, to investigate different patterns of social life in diverse parts of Chicago. This type of research was highly influenced by one strand of argument in the so-called *Methodenstreit*. This methodological dispute took place in late-19th-century Germany. It was argued by social scientists such as Georg Simmel and Max Weber that because human beings are complex and creative social subjects, their behaviors are neither caused nor explainable by standardized laws; thus, there is a fundamental difference between natural science and social science that requires the use of different methodologies.

The specific aspects of human interactions are notably elucidated by the social psychological theory of symbolic interactionism, according to which the activities and consciousness of the individual are considered part of social interactions. With the rise of positivism since the late 1920s, the use of qualitative research methods came under fierce attack. As a result of the argument that social research methods should lead to measurable and objective results, some methods

similar to those of the natural sciences came into common use. These are characterized by the statistical analysis of data gathered by experimental and survey research. Critics of this approach argued that positivists research a simplified, overly abstract version of the real world that ignores the rich meanings people construct and use in everyday life. According to this criticism, such research neglects the unintended influence on the research process by the researcher in his or her specific role. This argument is analogous to one from the natural sciences, that is, the uncertainty principle developed in 1927 by the physicist Werner Heisenberg, who demonstrated that the position of extremely small particles such as electrons could not be exactly specified because the process of its measurement itself changes the momentum and direction of the particle.

With the growing influence of positivist philosophy and statistical methods, however, qualitative methods lost much of their influence in the social sciences, particularly during the quantitative revolution in geography, starting in the 1950s. In consequence, the use of qualitative methods in human geography declined greatly in importance. Humanistic geographers such as Yi-Fu Tuan and Anne Buttimer in the 1970s, however, argued for a qualitative research perspective that was highly influenced by the philosophy of phenomenology. This approach is based fundamentally on the notion that the perception of one's surroundings is deeply conditioned by the biases, cultural norms, and cultural attitudes of the perceiver. Accompanying the growth of social theory in geography, the use of qualitative methods has flourished since the 1980s. Taking the appreciation of culture on the basis of individual everyday activities to be significant for research has greatly expanded the use of qualitative methods.

Characteristics of Qualitative Methods

The main characteristics of qualitative research methods are difficult to delineate, as several research methods are in use under the cover of this umbrella term. Some qualities can, however, be identified that are to a greater or lesser extent essential for the methods to be classified as qualitative research: Qualitative methods focus on the

profound implications of some individual cases and aim to explore observed cases in an open-ended manner instead of deducing their implications from rigidly conceived theories a priori. Furthermore, they incorporate the role of the researcher.

In-depth data—representing the meanings and routines of individual lives—are produced with qualitative methods through their focus on the deep structures of some individual cases. The people being researched are investigated in their role as subjects, considered as members of wider social contexts. The methodological aim is to conceive individual social activities as an integral part of a broader cultural context. During the interpretation process, the social logic and meaning that underlie these individual events must be teased out. This notion is at the heart of the concept of “thick description,” introduced by Clifford Geertz in his influential book *The Interpretations of Culture* (1973). Social interactions and experiences lie at the center of attention; for example, the meanings and routines in narratives are analyzed by observing everyday activities or by examining subtle body movements recorded on video.

Qualitative methods are open to the previously unknown because they do not attempt to test a hypothesis formulated before the research is executed. This task can be managed by providing those in the focus of research room to shape the process of inquiry itself. The specific meanings used by the investigated subjects should be included and taken seriously when formulating, and later reformulating, the research questions. As the subjects leave their marks on the process, the social scientist must act in a flexible manner. For this reason, qualitative methods can vary and can be applied in different ways.

As a consequence of the assumption that the results of research are not objective, subjective elements are considered as part of the qualitative research process. For example, the setting of the interview—where and under which circumstances it is conducted—must be considered. Qualitative research takes into account the perspective of the researcher, that is, his or her biases, assumptions, priorities, and positionality, and its influence on the research, since the researcher is situated and does not occupy a neutral position. The role and impact of the social scientist's subjectivity

and identities are considered in a self-reflexive way. The technique of self-reflexivity has been prominently developed in anthropology, as well as in the work of the sociologist Pierre Bourdieu, since the 1970s. In human geography too, self-reflexivity has its place; an example is the research on gender by Linda McDowell. This perspective is also prominently developed in postcolonial studies—for example, in the work of the geographer Alison Blunt. Postcolonialists demonstrate that the perceptions and outlook of many former colonized regions and their peoples are deeply conditioned by common stereotypes grounded in a lasting colonial perspective, the so-called imperial eye. This view can also be read as a critique of earlier anthropological field studies, which did not include sufficient self-reflexivity of their colonial perspective.

Producing Qualitative Data

Human geographers make use of a wide set of techniques for producing qualitative data, including several types of interviews, field observations, and analysis of objects and texts. Research projects often combine different techniques. In gathering data, it is essential to select a sampling strategy, which involves considering the choice of cases with respect to differences, for example, in ethnicity, class, gender, sexuality, religion, or age.

The most typical methods are various forms of interviews. Qualitative interviews are characterized by having the character of a more or less structured open discussion, where the interviewee is stimulated to influence the interview's content and course. The interviewer tries to gain knowledge of the interviewee's experiences and thoughts about his or her own life, or about topics where the interviewee has knowledge. Interview forms differ in the degree of their preliminary structure. While expert interviews are conducted with the help of an interview guide and contain at least broad questions or topics of interest, an ethnographic interview has a more spontaneous character and is held in a completely open manner. The autographic narrative interview form allows the interviewee to speak freely about his or her own biographical events. In its most radical form, such a format avoids interviewer-interviewee interaction within the interview, in consequence

of which it tends less toward an interview and more toward a monologue. In addition to one-on-one interviews, more people can be involved in the technique of focus group interviews. The strength of this interview form lies in the fact that speaking about a common topic or experiences with others allows people to have more time to reflect on and to recall their own experiences. Something that one person mentions can stimulate memories in others. In interviews, data are produced in the form of written transcripts. Depending on the kind of research, prepared transcripts range in their level of detail from simple notes to an exact (recorded) reproduction of the precise language used in the interview.

Observation methods are crucial, for example, in research on the interaction between everyday human activities and geographic places, which lies at the heart of human geography. In addition to the researcher's observations, participant observation is also used. In this method, the researcher participates in the everyday activities of the people being observed. In its most developed form, this approach can go as far as the researcher becoming a member of the observed social group and adopting their outlook and behaviors. As with interviews, data are created in the form of written field notes, as well as visually in photographs and video. These notes include observations about the situation being studied and occasionally some reflections on the researcher's own perspective and involvement.

Analyzing Qualitative Data

Data produced by qualitative methods require relevant analytical techniques. In addition to interview transcripts and field notes, sources for analysis are different forms of text, such as maps, landscape paintings, archival documents, diaries, films, or photographs, as well as material artifacts.

One of the main tasks of data analysis is that of coding and classifying the material. This job is best developed in the grounded-theory approach. In various steps, and often with the help of computer programs, the entire data corpus is thematically structured and linked. With this procedure, the same topics recurring in different interviews can be analyzed. Interpretations can be developed

on the basis of several examples, making it possible to identify similarities or dissimilarities.

In content analysis, the frequency with which different topics arise can also be identified and analyzed with the help of statistics. In discourse analysis, the topics that are included and the ways in which they are expressed can be investigated. Modes of thinking, talking, and acting that are not present in the material can be identified. Discourses are identified by their use in specific forms of talking or acting, as well as in distinctive patterns of places and architecture. Discourse analysis, which is grounded in the research of Michel Foucault, has been used in human geography since the late 1980s.

As qualitative data analysis can be carried out as a step-by-step procedure, at the same time as interpretations are organized and the internal logical structure of the argument is tested, the process of writing itself can also be part of the analysis.

QUANTITATIVE METHODS

The sudden rise of quantitative methods in geography in the 1950s and 1960s is often regarded as one of the greatest achievements in the discipline. Quantitative methods can be traced as far back as Thales and Eratosthenes, who were in their own right mathematical geographers in ancient Greece. However, the 1950s are thought to be the origin of modern quantitative methods in the discipline. The closing of Harvard's geography department in 1948 was an early indication of a crisis in the discipline concerning its inability to meaningfully explain processes or phenomena; this limitation included a lack of quantitative analysis that relegated the discipline to a classroom setting and inhibited its growth and utility in both private and public sectors. This entry describes the evolution of quantitative methods in geography during the 1950s and 1960s, reviews the use of descriptive and inferential statistics in the field, and examines the place of quantitative methods in the discipline of philosophy today.

The crisis of the 1950s confronted geographers with the task of deciding in which direction to take the discipline. Richard Hartshorne advocated a descriptive, traditional geography, while Fred Schaefer pushed for a quantitative analytical approach. Schaefer attacked Hartshorne's emphasis on idiographic regional distinctions in favor of nomothetic, lawlike statements to explain spatial patterns. This critique encouraged geographers to rethink the direction of the discipline in a way that would make it more quantitative, a reconsideration that led to the quantitative revolution. Some observers suggest that the quantitative revolution was logical positivist in nature, as positivism is an epistemology that privileges scientific methods, general explanatory laws, and quantitative data and methods as the highest and best form of knowledge. However, it is now acknowledged that quantitative geography and positivism are not synonymous, that is, positivists do not have a monopoly on the use of quantitative techniques (e.g., quantitative Marxists also use these methods).

Origins of Quantitative Methods in Geography

The use of quantitative analysis and spatial science in geography began at the University of Iowa and the University of Washington, as well as Northwestern University, during the 1950s. Elsewhere, Torsten Hägerstrand at Lund University was pioneering quantitative research in the 1950s in relation to innovation diffusion. In United Kingdom, Richard Chorley's work stands as a milestone. By the 1960s, the interplay of multivariate statistics, mathematics, computers, models, and an underlying scientific philosophy cemented the foundation of quantitative geography in the discipline.

The type of quantitative analysis often employed by geographers in the early years of the revolution was primarily descriptive. Inferential statistics or the drawing of conclusions from statistical samples became popular shortly thereafter. By 1970, geographers were using computers to help conduct multivariate quantitative analyses.

In human geography, quantitative techniques today are increasingly analyzed in conjunction with an understanding of social and economic processes and theories. The adoption of statistics in geography unfolded differently in different fields of the discipline. Economic and urban geography, for example, were far more receptive to quantitative analysis than cultural, political, or historical geography. In geographic information science (GIScience), physical geography, and remote sensing, statistics are used to measure and calibrate a phenomenon or technique. GIScience, for example, arose from GIS (geographic information systems) partly because of its ability to combine quantitative analysis and computer cartography. While quantitative geography waned slightly in importance during the retreat of positivism in the late 20th century, geomatics, GIScience, regional science, and remote sensing have reinvigorated the use of statistics in geography.

Descriptive and Inferential Statistics

Quantitative methods in geography are either descriptive or inferential in nature. Descriptive statistics are typically used to produce numerical

and graphical summaries about a data set or a sample population. Measures of dispersion, frequency, and central tendency typify descriptive statistics. Measures of dispersion include standard deviation, variance, range, and interquartile range. Frequency counts help describe the modal pattern of a sample or population; for example, is it normally distributed, bimodal, or skewed? Measures of central tendency are based on procedures that describe the mean, medium, or mode. All these descriptive techniques can be illustrated in tables, graphs, histograms, box-and-whisker plots, or box plots. In geography, means are often compared over time and space. For example, the mean temperature of various geographical areas by year can be analyzed to determine if climate warming or cooling is taking place on a temporal-spatial level. In geography, quantitative temporal-spatial analyses are typically conducted to analyze natural or human phenomena, such as tornadoes, hurricanes, earthquakes, rainfall, poverty, corporate headquarters, gentrification, or diseases, to name a few. The discipline of geography has come a long way in interpreting phenomena within a spatially autocorrelated framework, and it is now an academic leader in this area of quantitative interest.

Nonparametric techniques vary from parametric techniques in that they help show relationships within or between nominal or ordinal variables and are classified as being distribution-free. For example, the chi-square test is based on categorical or nominal data, and Spearman's rank correlation coefficient is based on ranked or ordinal data. Parametric statistics, on the other hand, such as analysis of variance (ANOVA) or Pearson's coefficient, assume normally distributed samples or populations. In the absence of such normality, a nonparametric technique is useful.

Inferential statistics are used to make inferences or generalizations from a sample to a population. The objective here is to make as accurate an inference as possible about a population and to determine if the relationship is statistically significant. To help determine the significance of an inferentially derived statistic, estimate, probability, or error values are calculated in conjunction with defined hypotheses. There are two sources of error that may prevent a sample from accurately

summarizing a population. These are sample error and sample bias. One quality of inferential statistics is that they attempt to control for sample error. On the other hand, sample bias cannot be controlled. One example of hypothesis testing would be to determine if the inventive capabilities of people from two regions are significantly different as measured by the number of patents. Using z or t test can help determine if any differences are statistically significant.

Inferential statistics also include bivariate and multivariate analyses. In this case, relationships between variables are typically examined using simple correlation, bivariate regression, Pearson's R , or pairwise correlation analysis. With respect to multivariate statistics, factor, principal component, cluster, discriminant, and multiple regression analyses are frequently employed. Geographers are particularly interested in using these techniques with spatially referenced data. For example, in an inferential multivariate analysis where each case is a region, researchers can extract and then map the residuals or scores from a regression, factor, cluster, or discriminant analysis to identify broad patterns or anomalies. Furthermore, by categorizing regions and their people, based on cluster or discriminant statistics, for example, one can yield invaluable spatial-consumer information. Such information is prized and sought in business and marketing. This approach, as well as other types of applied quantitative analyses in geography, has helped substantially to increase awareness of the discipline in the private sector.

Impacts of Quantitative Methods

The adoption of quantitative methods in geography has had a notable impact on the discipline. Their introduction facilitated positivist thinking as well as the use of neoclassical economic modeling. In this regard, techniques were borrowed from other disciplines and used to explain spatial processes and relationships. For example, the bid-rent curve, contextualized in von Thünen's land use model, is an example of neoclassical modeling that uses basic numeric methods. Waldo Tobler may have been the first to create a law in geography based on the gravity model. The model uses mathematical procedures to show that things, such as cities, are interrelated

and that near things are more related than distant things. Tobler's model has its inspiration in Newton's law of universal gravitation and has helped create statistical procedures unique to geography, known as geostatistics.

Quantitative analysis in geography helped with theoretical developments in the discipline. Today, modeling in geography has become much more sophisticated, as is the case with artificial neural network analysis in GIScience. The post-positivist movement has helped bring the discipline a long way from positivist quantitative analysis, and its impact has been real. For example, there is greater acceptance of economic geography courses on fashionable topics such as globalization, which seem less quantitative and positivist model based. Geomatics, on the other hand, is becoming increasingly quantitative and is helping to keep geography from sliding back on the quantitative "slide rule." One of the reasons for this is better data sources, for example, on the census or climate, which are becoming increasingly digitized and elaborate.

The nonpositivist approaches to geography in the 1970s led to resistance to quantifying human behavior. The notion that positive spatial science could provide realistic models was attacked. Though geographers could quantify the location and extent of urban poverty, for example, solutions to the problem seemed absent from the quantitative models. The growth of humanistic thought during the 1980s led to a further critique of quantitative models in geography as being inappropriate when applied to the behavior of thinking human beings. As simplified as the early quantitative models in geography seem, they continue to be useful in many respects. The bid-rent curve, for example, continues to help explain the distribution of economic activities within urban space. Similarly, the gravity model is useful in studying traffic patterns or migration. For example, gentrification often occurs near key transportation routes (particularly public transportation) and is bounded partly by distance to these routes. Today, quantitative methods in geography often incorporate or address social or scientific theories within different epistemological approaches. This meshing has lessened the quantitative/qualitative divide in the discipline. Quantitative methods are becoming increasingly more refined and powerful

in geography with the help of geotechnical innovations. For example, traditional regression modeling is overlapping geographically weighted regression and spatial autocorrelation analysis. These refined quantitative methods are helping to substantiate geography's role in the social and natural sciences.

QUANTITATIVE REVOLUTION

Quantitative revolution is the not very felicitous term that arose to describe the partial transformation of geography from a merely descriptive science into one that included the development of a theory of spatial organization and behavior, formal modeling of these processes, and the use of appropriate statistical methods to test the expectations from theory.

Participants preferred the term *scientific*, emphasizing a fundamental shift from an ideographic (descriptive) to a nomothetic (formal theory) epistemology. *Revolution* is accurate, as there was assuredly an intentional break with what had come to be viewed as an inherently

interesting and integrative field of study but one that had embarrassingly failed to go beyond “what” to the unsolved questions of “how” and “why.” Instead of providing maps and data as part of general education and for scientists in other disciplines to theorize about, participants were determined to begin to explain the patterns of human as well as physical processes on the land. The term *quantitative* arose from the novelty of the use of inferential statistics and the embracing of simple mathematical models, although the publications of almost all the “pioneers” of the revolution concerned mainly theory of spatial structure and movement.

The inspiration for the quantitative revolution was primarily theoretical, not statistical, most obviously in the work of Walter Christaller (central place theory), Torsten Hägerstrand (Lund University, diffusion and simulation), and Fred Schaefer and Thomas McCarty (University of Iowa), and at the University of Washington, Edward Ullman and especially William Garrison in turn influenced by the rise of regional science, which was initiated by Walter Isard. Beginning in 1958, a cadre of students spread the movement with revolutionary fervor, as courses in location theory and statistics arose in Chicago, Northwestern, Michigan, and, in the United Kingdom, Bristol and Cambridge. Systematic theory and statistics began to be incorporated into the wider curriculum in both physical and human geography.

Although it originated in the 1950s, by 1963 the new movement had succeeded in becoming a vocal and active presence at dozens of institutions, including most major departments with doctoral programs in geography. National Science Foundation (NSF)–sponsored symposia on quantitative geography facilitated the rapid growth, via the circulation of ardent and informative “discussion papers,” beginning at the University of Washington in 1954, and through publications in the leading journals.

The second decade (1964–1973) was one of institutionalization, as the theoretical revolution in fact succeeded in transforming geography, and then of the expected critique and counterrevolution. Institutionalization took two forms. Most important, yet underreported and underappreciated, was that the need and quest for theory

became incorporated into the fabric of the discipline, in research, in teaching and publication, and in all branches of the field. Less universally, common statistical procedures were used almost routinely in evaluating the results of research. Significant numbers of theoretical expectations about locations of firms and activities, urban structure and change, trade and transportation, administrative organization and electoral behavior; migration and communication, just to mention a few areas in human geography, were verified or found wanting. By 1973, the “new geography” had been incorporated in texts as well as journals, for example, *Geographical Analysis*, which began in 1969.

The second form of institutionalization was through specialization and deepening of both method and theory and continuing through the present. Having originally adopted the already prevalent statistical procedures and models, geographers increasingly developed new methods of spatial analysis, including those dealing with serious issues of spatially ordered data, and laid the foundation for GIS (geographical information systems) and a further revolution in spatial representation. Methodology expanded to encompass qualitative approaches, if they contributed to verification of theory; that is, research might use both quantitative and qualitative tools. Theories of location, spatial organization, movement, and diffusion became more sophisticated and realistic and were broadened to deal with complex social structures and uncertainties of behavior and with the interface of physical and social processes. As even severe critics have acknowledged, the wider legacy of the quantitative revolution has been a deeper appreciation of the central role of theory.

The successful institutionalization of scientific theory and method within geography had two overwhelming benefits. Most essentially, it saved geography’s standing as an advanced and respected discipline, as marked, for example, by its presence in the National Academy of Sciences and its role in the GIS revolution. Practically, it led to the creation of myriad opportunities for consulting and nonacademic jobs in the private and public sectors, as well as enabling the enormous growth of the discipline—with room for its critics and detractors!

Revolutions spawn counterrevolutions. Again, this took two forms, both under what came to be called “critical” geography. The dominant critique was on the substance of much of statistical and theoretical work, which early on seemed to concentrate on explaining how the existing social system was supposed to work but which neglected wide areas of human experience and social reality—other social systems and the inherent vast inequalities in power in the dominant social system in terms of gender, class, place, race, or level of development. These critiques unleashed new waves of fervent development of theory, but they should be viewed as challenging and renewing the spatial analytic, spatial science paradigm of geography, not replacing it—for example, poverty and racial inequality as geographic manifestations of social processes. On the other hand, to the extent that theory was expounded that was intentionally untested or untestable, geography has been diminished.

A secondary critique, in part valid, is that for too many geographical methods, techniques and technology have replaced or substituted for theory; that is, there is undue concern about precisely measuring the socially irrelevant and unimportant. The philosophical critique of quantitative methods is more basic and questions the very idea of scientific truth or the need to verify theory—that knowledge itself, and the language we use, is relative and changeable. The legacy of the quantitative revolution is the very existence and strength of a geography transformed into a modern science, devoted to theory that explains spatial organization and behavior and is generalizable, communicable, and verifiable. The quantitative revolution may be over as a phenomenon, but the battle over the meaning of geography as a science continues.

QUEER THEORY

While “queer” as an analytical category emerged out of a poststructural critique of identity in the humanities, queer theory has been adopted by geographers as a tool to both understand and complicate topics as (seemingly) divergent as theorizations of identity and globalization. Although the earliest impact of queer theory in geography was most obvious in scholarship on sexuality and space, its influence can now be seen within a much greater variety of research.

In scholarship and in public fora, the word *queer* is commonly used both as a synonym for gay, lesbian, bisexual, transgender, and/or

questioning (GLBTQ) identities, or to indicate a combination of these identities, and as a term to signal the instability, or refute the stability, of these very identity categories. As many suggest, however, the use of *queer* as an umbrella term for sexual identity oversimplifies its potential as a theoretical tool. Instead, the utility of queer theory stems from its function to question or disrupt that which is considered “standard” and “normal” and to attend to the permeability of the boundaries, and binaries, on which “normal” is predicated. Under this framework, identity is understood as fluid and constructed in a way that is neither static nor essential, nor neatly bound by a heterosexual/homosexual binary that is otherwise presumed to be natural. Moreover, queer theory decouples gender identity from sexuality, desire, and sexual practice; in doing so, it calls into question the heterosexual matrix, or the socially prescribed relationship between sexual expression, body identity, and gender performance that is often taken as a given rather than as a historically and contextually specific regulatory framework.

Yet challenging the taken-for-granted organization of (sexual) identity is only one facet of queer theory. More broadly, it is applied to question normative constructs and social institutions: Queer theory seeks to both make visible and deconstruct formations, such as nation and capital, that have emerged from a particular, approved set of social relations. Luibhéid and Cantú (2005), for example, demonstrated that processes such as migration, citizenship, and nation building operate in relation to notions of normative sexuality, even as sexual identity remains a central issue for individual migrants (through institutional procedures such as reunification for spouses or other permitted familial relations). Sexuality, however, is situated within a broader context of power relations; to continue with the above example, migrants are policed on the basis of various categories, such as race and national origin, over and above sexual identity. Ideally, then, queer theory must account not only for the role and function of sexuality but also explore how sexual identifications and enactments are differently marked along lines of race, class, ability, gender, and other identity markers. For Luibhéid, among others, a queer analysis of migration requires attention to various

Supporters of same-sex marriage wave flags before the start of a rally at the Pentacrest in Iowa City, Iowa, celebrating the Iowa Supreme Court ruling upholding a lower-court decision legalizing same-sex marriage on April 3, 2009. The rainbow flag as we know it today was developed by San Francisco artist Gilbert Baker in 1978. Baker explained that his colors each stood for a different aspect of gay and lesbian life: hot pink for sexuality, red for life, orange for healing, yellow for the sun, green for nature, blue for art, indigo for harmony, and violet for spirit. The pink stripe was later removed because the color was not available commercially for mass reproduction.

mutually constitutive processes through which migrants, “citizens,” and the nation are continually (re)produced.

Not all queer theorists take an intersectional approach to multiple axes of power, however. Thus, the theory has been critiqued for reproducing racial exclusions under the guise of a de-raced and de-gendered subject, which has the effect of recentering a universal white gay male subject while ignoring the material privileges available to this subject position. Queer theory does take up the question of privilege, but it often does so through a critique of assimilation. Accordingly,

gay and lesbian liberation movements that seek to assimilate within, rather than contest, larger societal structures are construed as homonormative and a sanitized version of radical queer politics. The U.S. same-sex marriage movement is often cited as an example of an assimilationist strategy. Critics charge that the effort by gays and lesbians to seek an equal right to marry in an unequal, consumption-driven society is akin to ignoring the logic of an unjust system that rewards gays who are focused on their domestic, individual needs and punishes those who do not conform to this normative model. As Natalie Oswin (2005)

points out, though, there is a danger in positioning a complicit, consumer-oriented gay in opposition to an “authentic,” radical queer; Oswin argues that we must reexamine the framework that situates radicalism and complicity as an invariable binary.

Oswin is among the many geographers who have contributed to and applied queer theory. Unsurprisingly, a critical engagement with the relationship between sexuality and space has been a central contribution. Many argue, however, that much of this scholarship remains confined to the treatment of gay, lesbian, and bisexual identities. These scholars advocate a move beyond these limits, to examine how *all* sexualities are historically, temporally, and spatially constituted and, therefore, how they are performed in myriad contexts, times, and spaces. Furthermore, as Puar, Rushbrook, and Schein (2003) suggest, putting queer theory to work in the discipline entails disrupting neatly defined boundaries within and beyond the scope of sexuality. For Puar et al., queering geography means examining the ways in which positivism is enabled by and dependent on dichotomous and absolute relationships and the ways by which positivist binaries reify neocolonial epistemologies.

R

RACE AND EMPIRE

The legacies of geography's historical complicity with the racialized logic of empire are profound and have had significant impacts on the ways in which race, racism, and racialization have been approached within geography. The geographies of empire from the late 19th century through the early 20th century demanded attention to a theorization of race; however, as Britain's imperial ambitions waned, the centrality of the study of race within the discipline was displaced. Race became closely entwined with various colonial efforts, and geographers were often complicit in this process. This is not to say that the study of race ceased to be part of geographic thought, but it certainly did not hold the same place within the discipline following World War I. In understanding the history of the geographic study of race, one must understand the role that geography played in the theorization of environmental determinism and its use as a tool of empire.

While the notion of geographic determinism certainly predates modern geography—it can be found within the pages of Aristotle's *Politics*—the mobilization of a scientific study of the geography of race took on new dimensions during the 19th century as the imperial ambitions of Western Europe and the United States relied on the modern discipline of geography to underscore and justify the racist thinking at the heart of their geographic expansion. The cementing of the

complicit relationship between geography, race, and the ambitions of empire marks a significant event in the history of the discipline. As Peet (1985) put it, “Environmental determinism was geography’s entry into modern science. Determinism attempted to explain the imperial events of the late nineteenth and early twentieth century capitalism in a scientific way” (p. 310). Thus, it is as a tool of imperialism, through the theorizing of the relationship between race and geography, that geography secured its place within the modern academy (Figure 1).

In fact, the history of geography and its role in carving up the globe to facilitate the domination of Western imperial powers is well documented. As Kobayashi and Peake (2000) explain,

From its origins in exploration and scientific classifications, the discipline played a founding role in establishing the systems of imperialist expansion and colonial power through which the Western world became a dominant center and its white inhabitants became normative, authoritative, and privileged. . . . The discipline of geography received its own legitimization as a result of the inimitable relationship established between colonial power and the map as a “rhetorical device of persuasion to justify the authority of its practitioners” assertions. (p. 399)

In this way, geography provided the “scientific” underpinnings for the common notion that the world’s cultures were entirely reflective of the physical environment, particularly climate. In

Figure 1 Geography school atlas illustration from 1883 illustrating the world's hierarchy of races as asserted by European colonialists. As Europeans conquered the world, racism became a significant part of their worldview, often used to legitimize their domination of non-Western peoples.

doing so, the science of geography reinforced a racialized conception of the world that established whites as the “natural” masters of the globe’s diverse peoples.

Moreover, geography’s previous role in providing the theoretical tools for the racialized logic of empire continues to cast shadows on present-day theorizing. “The contemporary discipline remains insufficiently critical of its past, and therefore reinscribes many of the racialized metaphors upon which it was established” (Kobayashi & Peake, 2000, p. 399). However, the shadow of the legacy of geography’s role as a science of empire has not handcuffed the discipline entirely. Much of the most exciting contemporary work of theorizing and critiquing the present forms of racialized imperialism has come from geographers and others using the insights of geographic theorization.

Some of the work that has broken from this norm and connected the past practices of imperial geography and colonial cartography to present-day forces of empire includes an examination of Western property rights and planning regimes and the legacies of dispossession on the marginalization of Aboriginal people in urban spaces within Canada, work tracing the shadow of the British Empire on the landscape of contemporary world cities, theorizations of ongoing racialized violence within white-settler societies, projects exploring the long shadow of slavery and exploitation on black geographies, and work on the “colonial present” in the Middle East. For many scholars, the discipline of geography provides the theoretical tools for understanding and challenging contemporary racialized logics of the projects of empire. What is clear is that the racialized forces of empire extend beyond the geopolitical order of the 18th and 19th centuries. Given the fundamental way in which an empire maintains a clear spacialized logic, the discipline of geography is well positioned to provide the tools of theorizing the present-day forces of empire and race.

RACE AND NATURE

Race and nature typically appear to be “natural” rather than social categories. People inherit their race genetically, and nature—whether in the form of a wilderness area or a person’s fundamental character—is by definition that which lies outside culture. Yet two bodies of scholarship, critical race and social nature studies, have challenged the naturalness of race and nature. This entry explains the main tenets of critical race and social nature scholarship and explores some of the ways in which critical geographers and other researchers have brought together in productive ways insights from the two areas of study.

Critical Race Theory

Critical race theorists, seeking to understand the making and maintenance of racial hierarchies, have shown how racial categories shift over time and across space and have thus effectively challenged the notion that race has a basis in biology. Instead, they find race rooted in history and culture and consider European imperialism key to the creation and naturalization of racial categories and to the assignment of social significance to the physical markers of difference.

In her 1992 influential work on European travel writing, Mary Louise Pratt examined how the Swedish naturalist Carl von Linné's (Carl Linnaeus) plant classification system, first introduced in 1735, reordered the natural world according to a European logic while at the same time making it appear that the system simply described the world as it already existed. But, Pratt shows, Linné classified more than plants. By 1758, he had classified humans into distinct types, which included the Wild Man, the American, the European, the Asiatic, and the African. Linné assigned physical and behavioral characteristics to each type, and the types appeared to exist as a part of nature. The European, for instance, appeared fair, blue-eyed, inventive, and governed by laws, while the African was black, flat-nosed, indolent, and governed by caprice. As Pratt points out, Linné's Eurocentric system not only encouraged comparison among human types but also naturalized the myth of European superiority.

The belief in European superiority, as many scholars have pointed out, was central to the colonial project. If Europeans existed on the highest plane of civilization, then surely the imposition of their religion, laws, and values onto "less civilized" peoples and lands was a justified and even noble pursuit. With the rise of scientific racism in the mid 19th century, European superiority and non-European inferiority came to appear as biological facts rather than surmountable cultural conditions, and various "scientific" strategies emerged for assessing the relative position of human races—for example, measuring the length and shape of heads of people of different races. Although the scientific value of such strategies has been undermined, scientific racism worked to make both race and racial hierarchies appear

natural and, thus, to justify European colonialism and its embedded racism.

Critical race theorists, in tracing the social production of race both historically and in the contemporary moment, denaturalize racism as well as race by revealing it as the practice of appealing to markers of difference that are culturally rather than naturally constructed. Racism connects to power because race seems natural. Revealing race as social therefore presents one way of disempowering racism.

Social Nature Scholarship

While appreciating their insights as foundational to her own work, the cultural geographer Kay Anderson has pointed out that critical race theorists have largely avoided interrogating the nature of nature, often taking nature for granted as the nonsocial ground on which social race is built. In her recent book on race and nature, Anderson suggests that race scholars are, not surprisingly, hesitant to invoke nature, since they have struggled to remove race from the category of the natural, showing it instead to belong to the sphere of culture and politics. Yet, and as shall be discussed further below, Anderson considers questioning nature central to a project that aims for a rigorous understanding of the history of race as a social creation.

In asking questions of nature, Anderson is joined by a group of scholars, many of whom are geographers, who contend that nature is not as natural as it seems. Like race, nature is social. Social nature scholars do not mean to suggest that humans physically make all parts of the non-human world or that humans are the only subjects involved in the construction of nature but rather to assert that there exists no ahistorical, apolitical, external nature. Humans have always constructed nature, both physically, by cutting down trees and building dwellings, for example, and imaginatively, for instance, by considering a wilderness preserve to be a natural area and an urban park to be a cultural space.

Social nature scholars, who often take their cue from feminist critiques of the nature-culture binary, consider Western cultural practices to be largely responsible for creating a false opposition between nature and culture. The appearance of

two separate realms of nature and culture is a product of culture rather than nature, and in reality, there exists only one hybrid realm of nature and culture. Certainly, the lake water piped into city dwellers' homes and the trees turned into newspapers on their doorsteps disrupt the idea of any clear distinction between external nature and human culture.

Research in social nature tends to examine the social and historical processes and relationships of power and inequality through which nature has come to appear separate from (especially Western) culture. In his 1996 seminal work on wilderness, for example, William Cronon shows how the concepts of the sublime and the frontier allowed upper-class white men in the 19th century to create the American wilderness as a site of culture-free nature. This human construction of nature did not exist solely in the imaginations of those who could afford wilderness vacations but was also engraved as nature into the landscape of the United States—for instance, in the form of national parks. Cronon's observation that the idea of an uninhabited wilderness could not exist without the prior eviction of the First Nations peoples from their territories underlines both the materiality and the power of social constructions of nature. Through placing Aboriginal peoples on reservations, the imagined empty wilderness came to exist in reality, while Aboriginal bodies and claims to territory were erased from the landscape. Like race scholars, those interested in examining the interplay of nature and culture are often concerned with issues of justice, studying not only how but also for whom and with what consequences nature has been socially constructed in different historical moments and geographical locations. Social nature scholars usually emphasize the environmental as well as the social impacts of particular constructions of nature, thus drawing the nonhuman world into their sphere of concern.

Cultural Politics of Race and Nature

Although critical race and social nature scholars both question the categories that seem self-evidently natural, their work has not overlapped to any great extent. Recently, however, a body of scholarship that traces connections between

social and historical constructions of race and nature has emerged and has demonstrated that race and nature often work together to make particular social formations and hierarchies appear natural. This scholarship is concerned not with what race and nature *are*—beginning instead from the premise that neither race nor nature possesses an inherent essence—but rather with what they *do*—that is, how they work together in different geographical locations and historical timeframes to effect and naturalize specific power relationships among humans and between humans and the nonhuman world. Scholarly work within the field of what Donald Moore, Jake Kosek, and Anand Pandian have referred to as the cultural politics of race and nature has the potential to deepen critical geographers' understanding of the complex interconnections between race and nature.

European Racial Thought During Colonialism

One key area that scholars of race and nature have illuminated is the study of European imperialism and colonialism, showing that the diverse projects of European rule worked through the co-constitution of race and nature (alongside other social categories such as gender). Bruce Braun, for example, has detailed historical and contemporary processes through which British Columbia's temperate rain forest came to be imagined and treated as a site of empty nature. He argues that there is nothing natural about the wilderness character of the region and shows how one cultural construction of nature came to dominate over others while appearing to be the result of nature rather than culture, power, and politics. Central to this process was not only the representation common within the colonial discourse of Native peoples as primordial and uncivilized and therefore undeserving of land but also the construction of the land itself—in geological surveys, art, forest industry rhetoric, and environmentalist representations—as an empty wilderness to be exploited or protected. As Braun shows, the characterization of the British Columbia forest as a natural space has had the effect of displacing the First Nations' cultural understandings of, and claims to, the same

land, thus authorizing the non-Native people—the government, the forest industry, and the environmentalists—to regulate, harvest, and speak on behalf of the forest.

Kay Anderson has taken a different approach from Braun on the question of race and nature to better understand European racial thought during colonialism. While Braun examines the implication of social constructions of nature in the operation of colonial rule, Anderson focuses on the ideas about race and nature embedded in European definitions of humanity. Specifically, she sets out to explain why the idea of race as innate rather than cultural arose in mid-19th-century European thinking and argues that the rise of what she calls “innatism” must be understood within a longer history of European thinking about the nature of humanity as it was shaped by colonial encounters with the indigenous Australian peoples and landscapes.

While Europeans defined humanness as the ability to transcend external nature (through agriculture) and corporeal nature (through reason), their encounters in Australia with peoples and places that bewildered their systems of understanding led them to a crisis in their belief in human distinctiveness. But this crisis, instead of leading to the breakdown of the belief that there existed a clear divide between humans and the nonhuman world, resulted in a new division of humanity into biological races, which allowed for the preservation of the idea that at least some (primarily European, male) humans could still fit comfortably into the category of the human. By attending to how European concerns about race, nature, and humanity shaped the emergence of innatism, Anderson’s account leads to a more nuanced understanding of the operation of race in colonialism than an approach that considers race only as a means of legitimizing empire.

RACE AND RACISM

Race is a marker of difference among humans based on physical features such as skin color or hair color/texture. Historically, race was treated as a biological or “scientific” method of human classification, in which racial “groups” were defined by the presence or absence of particular inheritable traits. This argument was tied to failed theories such as social Darwinism—which applied Darwinian notions of competition among species to competition within the human population—and environmental determinism, which argued that particular social traits were inherent to people living in particular places due to the environmental and climactic characteristics of each place. These theories were developed during the colonial era and were used by those in

power to rationalize the exploitation or extermination of particular “racial” groups. The scientific basis for race has since been refuted, as multiple studies have shown that there is greater genetic diversity within racially defined groups than exists among those groups.

Simply put, there is no biological basis for race. Yet, despite its failings as a scientific concept, race today exists as an extremely important socially constructed conceptualization of differences among humans. That race is such an important concept is the result of racism. Racism is the ideology of difference, which takes as its foundation the idea that particular (usually negative) attributes regarding behavior, intelligence, or culture are inherent within particular racial groups. This ideology is then used to justify arguments for the superiority of one racial group relative to another, which leads to the production of inequality between racial groups.

The normative understanding of racism is often limited to acts of violence, malice, or economic exploitation that are motivated by racial prejudice. Examples of these types of racism are hate-based crimes, or decisions by employers not to hire workers on the basis of their race. This narrow definition of racism does not acknowledge the informal ways in which racist ideology has been incorporated into economic, legal, educational, and other societal structures. The following sections discuss the dominant theoretical engagements with race and racism in geography, as well as some of the methodological challenges inherent to research on race/racism issues.

Critical “Race” Studies in Geography

Critical racial theorists engage in a type of ethically motivated antiracism research agenda. Rather than treating race as an objective category, they use social constructionist theories to illustrate the way in which the idea of race is mobilized in various contexts to exploit, disadvantage, or otherwise disempower particular racially defined groups of the population. In critical racial theory, racial categories provide the framework for a set of power relations that protects the dominant group’s position of power. The process through which racial ideology is applied to social actors (who should be understood as not just

people and processes located in places but also as landscapes, systems of governance, education, or any other socially produced phenomena) is known as *racialization*.

The Social Construction of Race

The argument that race is a socially constructed category and ideology rather than a biological or “natural” method of human classification is based on social constructionism, which challenges arguments for the “naturalness” of human organization systems, the categories within those systems, and the ideologies on which those systems are founded. In this perspective, the argument for the “naturalness” or “commonsense” use of particular methods of social categorization is rejected outright. These ideologies are then subjected to critical examination, which can serve to expose the power relations that make clear the basis for defining the concept in a particular way given the specific historical and geographic context.

In the case of race, critically examining the way in which racial groups are defined varies geographically and has varied significantly throughout history. These variations and historical redefinitions typically have served to rationalize the exploitation of one population by another. The term *race* has been applied almost exclusively for the purpose of rationalizing the subjugation of one group by another, regardless of the particular characteristic by which the supposedly inferior group was defined. For example, the British comfortably interchanged the concept of race with political nationality in their subjugation of the Irish “race.” The Nazi Party in World War II sought to exterminate the Jewish “race,” despite the fact that religion is not a biologically inheritable trait.

That race exists only as a social construct does not lessen the power of racism as a mode of social organization. The fact that people believe and behave as if race does exist makes it a social reality with material effects.

Geographic Contingency of Race/Racism

One of the ways in which geographers have contributed to research on race and racism is by illustrating how racialization processes are

geographically contingent. Racialization refers to the process by which one comes to be viewed and/or views oneself as belonging to a particular racial group. The way in which people are racialized is highly dependent on where this process takes place. Socialization processes are both embedded in place and connected through space such that socialization processes and geography are interdependent, not simply complementary. Geographers understand places as socially produced as well. Within this framework, places are not lifeless boxes within which social production occurs. Racialization processes are themselves shaped by, and affect, the social construction of places. This constitutive relationship between social processes and places creates a larger racialized landscape, which provides the context for how racial categories are normatively defined.

Critical theorists argue for a relational understanding of race and racism. This means that the way racial categories are understood—the meanings attached to a specific racial group—can only be understood as they relate to other races. This relational understanding allows for a movement away from understanding race as a binary relationship (civilized/uncivilized, white/nonwhite) to an understanding of racism as a set of power relations acting in a specific time and place. These power relations restrict individual and group access to power and resources relative to the dominant group, which in Western societies is most often defined as the whites. The severity of this disempowerment depends on the particular racial identity of the group in question, as well as the geographic context.

Relational perspectives on race understand racism as the result of racial hierarchies within a social system of white privilege. White privilege refers to the set of power relations that supports the status quo position of whites as the recipients of any number of advantages simply due to their being white. In this system, “whiteness” is the norm against which all other races are evaluated. These privileges are wide-ranging and include access to better educational and economic opportunities, access to better housing than equally qualified minorities, and being underexposed to pollution relative to minority groups, just to name a few. Geographers have done a great deal of research investigating how

these types of inequalities are spatially distributed and maintained through spatial relations. Economic relations—segregation and housing—and environmental racism are research themes that guide geographic research investigating each of the specific material effects of racism and white privilege listed above, respectively.

Racial hierarchy is a metaphor used by advocates of the relational perspective to map the effects of power relations on multiple racial groups in a particular time and place. In a racial hierarchy, racial (or ethnic) groups are positioned in a hierarchical manner based on their disempowerment relative to all other racial groups. Within the social system of white privilege, whites would be at the top of the racial hierarchy, with all other racial groups somewhere below. Racial groups’ positions are conceptualized as distinct but subject to change in particular geographic and historical contexts. The ability to affect the position of other racial groups within the racial hierarchy is yet another aspect of white privilege.

Racialized Landscapes

Processes of racialization are not limited to human bodies and processes of identity formation. Because race is a hegemonic ideology in contemporary society, all elements of social life are racialized. Processes of racialization attach racial understandings to places and landscapes at every scale: continents, nations, states, cities, neighborhoods, and even within the home. Racialized landscapes are a particularly important part of geographical understandings of race and racism because popular understandings of landscape provide context for people’s life experiences. Therefore, racialized understandings of landscape shape the way in which individuals interpret their own life experiences, and simultaneously serve to reinforce existing hegemonic understandings of racial categories. A few common examples of racialized landscapes in the United States are “the ghetto” and “the border,” which are “minority” landscapes, and “suburbia,” which is a “white” landscape. These racialized understandings of landscape police who or what “belongs” in a particular place and have material effects on a wide range of social issues, from property values to law enforcement practices.

Quantitative Approaches

Despite the widespread acknowledgment that race is a socially constructed and problematic method of human classification, many researchers still use race as a social category for quantitative analysis. In quantitative research, race is treated as an objective category and method of human differentiation. This is not to say that these researchers are unaware of the problematic nature of defining racial categories. There is a wide spectrum of researchers involved with race-based research, within which there are great disparities in the level of critical engagement with the idea of race. What all quantitative approaches to race studies have in common is their dependence on race counting.

Among those engaged in antiracism work, there is considerable debate regarding the merits of race counting. On the one hand, racial counting provides quantitative data that researchers and activists can use to demonstrate the material effects of racism in society. On the other hand, the practice of recording data according to race supports the very ideas about racial difference on which racism is based. Herein lies the greatest challenge for those who wish to eliminate racism as a hegemonic form of social organization in society. For example, it would be impossible to demonstrate the extent of residential racial segregation without collecting data that categorize residents by racial group. One could demonstrate spatial inequalities in access to public transit or economic opportunities without using racial data; however, without using data that categorizes people according to race, it would be impossible to demonstrate that those spatial inequalities disproportionately affect neighborhoods with a high percentage of minority residents. Antiracism researchers are thus faced with an ideologically contradictory choice, because they cannot quantitatively demonstrate the material effects of race-based disempowerment in society without implicitly supporting the idea of race as a system of social categorization.

Assigning Race and Counting Racial Groups

The history of recording racial data for enumeration purposes is firmly based on institutional

racism during the pre-Civil War era in the United States. The first U.S. Census included racial data, in accordance with the Three Fifths Compromise, which was negotiated between the southern states, in which slavery was legal, and the northern, “free states,” where it was illegal. The purpose of the compromise was to increase southern political representation in Congress. In this agreement, each African American slave was to be counted as three fifths of a person for the census and representational purposes.

The racial categories used for population research vary depending on the scale and location of the survey. Over time, the U.S. Census has been adapted to better incorporate “new” races, such as “Native American” or “Asian or Pacific Islander” and to allow for members of any racial group to self-identify as ethnically Hispanic or non-Hispanic. For the first time, the 2000 U.S. Census allowed respondents to self-identify as more than one race. The incorporation of multi-racial responses on the 2000 U.S. Census created 63 racial categories. This creates new challenges for geographers and demographers attempting to project changes in the racial composition of a population. Because of the seemingly constant adaptations being made to the racial enumeration process, some argue that the way in which racial categorization is done says more about the racial politics of the era than any future trends that can be projected based on the data created. If this is indeed the case, then the recent changes to the U.S. Census can be understood as a government response to the collective demand of individuals who identify themselves as multiracial for a more accurate representation in census records.

Some have argued that the increasing complexity of race-counting processes will inevitably lead to “the end of race” because quantitative population projection models simply cannot account for the shifting cultural perspectives on interracial marriage and interracial birthrates, death rates, infant mortality, and so on—all of which are vital to the accuracy of population projections. In this limited sense, society may indeed be nearing the end of race-based studies. It would be quite premature, however, to argue that the failure of models that depend on racially differentiated data sets is indicative of “the end of race” in society. In fact, the diversification of racial counting

practices can impede the efforts of antiracism activists. Racism is not the result of self-selected identity categorizations. Rather, racism is a system of differentiation in which dominant groups assign membership in a particular racial group to individuals. For example, individuals with parents of different “races” may view themselves as multiracial and still face the same discrimination and disempowerment as those who self-identify as belonging to a single minority racial group. Therefore, racism cannot be eliminated as a hegemonic system of social organization simply by altering the ways in which individuals understand their own racial identity or by expanding the number of racial categories in a census.

segregation researchers make their homes in numerous disciplines such as geography, sociology, demography, political science, and urban studies. Research on racial residential segregation shares a history with the examinations of immigrant settlement and assimilation, which began with the Chicago School of Sociology in the early 20th century. Historically, spatial integration of foreign-born groups with the white majority population has long been viewed as reflective of a broader structural assimilation. However, numerous critiques have been leveled at many of the assumptions underlying the now multiple variants of immigrant assimilation models, many of which trace the geographic trajectories of residential settlement over time.

The vast majority of racial segregation research in North America since World War II has focused on the degree to which African Americans and whites share (or do not share) residential space in contemporary urban contexts. Most studies have used U.S. Census data to examine residential patterns within and across large metropolitan areas, frequently tracing identifiable segregation patterns over time. Over the past few decades, segregation researchers have employed multiple segregation indices developed to assist in measuring the degree of spatial separation between racial groups. The most common of these indices undoubtedly remains the Dissimilarity Index, which measures the degree of spatial evenness in the residential distribution of one racial/ethnic group across subunits of a geographic area. Thus, the Dissimilarity Index is interpreted as the percentage of members of a given racial/ethnic group that would have to move to a different neighborhood for the percentage of each neighborhood to equal the percentage of that group across the larger geographic area (typically an entire metropolitan area). As measured by the Dissimilarity Index, segregation between African Americans and whites in U.S. metropolitan areas reached its height in the 1960s and 1970s and was exacerbated by increased suburbanization and “white flight.”

In a seminal paper, Massey and Denton (1988) outline four other indices that measure different forms of segregation: exposure/isolation, centralization, clustering, and concentration. Massey and Denton propose that when groups are segregated along four of the five aforementioned dimensions,

RACIAL SEGREGATION

Although racial segregation is inherently a geographic phenomenon, social scientists from numerous disciplines continue to contribute to the research literature. Today, racial residential

they are “hypersegregated.” Analyzing the 1980 U.S. Census data, Massey and Denton found that such “hypersegregation” was characteristic of the experiences of African Americans in 16 metropolitan areas (when measuring African American/white segregation patterns). A follow-up study by Kaplan and Holloway (1998) using the 1990 Census data showed little change, as African Americans remained hypersegregated from white residents in 14 of those 16 metropolitan areas, while several additional metropolises joined the hypersegregated list. Wilkes and Iceland (2004) concluded that by 2000, there was an overall decrease in the number of black-white hypersegregated metropolitan areas in the United States (which had decreased from 29 to 23), yet new hypersegregated cities had emerged when examining the degree to which Hispanics/Latinos share urban space with white residents. Because of the broader demographic shifts that have occurred over the past three decades across the United States, racial segregation researchers have begun to widen their foci to examine the contemporary spatial residential relations of Hispanic and Asian residents in many metropolitan areas.

While the geographic patterns may be relatively clear, the causes and consequences of racial segregation vary immensely depending on the geographic and historical contexts. Early-20th-century segregation patterns resulted from institutionalized (often legal, state-sanctioned) discriminatory practices in mortgage lending and housing opportunities in many North American cities. Today, economic status frequently serves as a focus for segregation researchers seeking to untangle the complex web of factors responsible for continued residential segregation. Similarly, researchers have examined the impact of choice or preference in efforts to account for extant racial segregation patterns. Studies have consistently concluded that economic status does not fully account for the geographies of racial segregation in contemporary

America. Similarly, voluntary or self-segregation alone does not adequately explain the persistent residential segregation by race and/or ethnicity in metropolitan areas of the United States today. Although no longer legally sanctioned and defended, discrimination in housing and mortgage lending continues to adversely affect minority groups disproportionately, such that “race,” although a social construct, remains a very real factor shaping contemporary geographies of residential settlement in the United States in the 21st century. Finally, isolation of minority groups particularly in urban areas can be seen as both a cause and a consequence of persistent poverty in these contexts. Regardless of the potential causes outlined previously, such spatial isolation of minority groups in cities frequently constricts opportunities in education and occupation for many residents. Although residential segregation and poverty are not inextricably linked, some of the same structural forces are at work in contributing to the current patterns of segregation and poverty in North American cities.

Recently, more critical approaches to studying “race” in the social sciences have begun to question the use of “white” as the standard or norm against which the racial segregation of minority

groups is measured and discussed. It should be noted, furthermore, that numerous researchers studying “race,” racism, and processes of racialization today are somewhat wary of the use of racial categories and quantitative data sets, such as the U.S. Census, citing their potential to perpetuate problematic notions of presumed biological/natural racialized identities, which are in actuality social constructions. Therefore, researchers engaged in racial segregation research today increasingly are wont to approach their work with the caveat that they view racial categories as socially constructed and thus malleable and shifting across both space and time.

RADIATION: SOLAR AND TERRESTRIAL

Radiation is the only commonly occurring form of energy that can travel through the vacuum of outer space. Solar radiation arriving at the Earth from the sun provides the energy that creates our climates and, through photosynthesis, plays a major role in the activities of the biosphere. Terrestrial radiation, emitted by Earth’s surface and atmosphere, returns that energy to space. The amount of energy in both forms varies with time and space: Short-term variations are responsible for producing weather, lengthier ones create seasons, and long-term fluctuations lead to climate changes. The major factors causing variations can be considered by tracing the solar radiation downward through the atmosphere to the surface and the terrestrial radiation up from the surface through the atmosphere and out to space. Over the long term and on a global scale, there is an approximate balance between incoming solar radiation and the outgoing terrestrial radiation, ensuring that climate changes are slow and small. Human activity, including the introduction of additional greenhouse gases into the atmosphere, is currently changing that balance and thus influencing climate.

Electromagnetic Radiation

Radiation is a form of energy emitted by everything that has a temperature above absolute zero. Formally it was known as “electromagnetic radiation” since it involves electromagnetic forces with the components of an atom. Our current understanding of this form of energy gives it a dual nature. First, it can be conceived as a series of small bundles of energy, called photons, which travel at the speed of light and vibrate as they travel; the greater the number of photons, the greater the amount of energy. Because of this vibration and forward movement, photons appear to be propagated as a series of waves, so our second concept is of radiation as a series of moving waves. The two concepts are closely related, and the fundamental laws governing radiation indicate that the higher the temperature of the

emitting body, the shorter the wavelength and the higher the energy of the radiation.

In practical terms, we can conveniently divide the “bodies” doing the emitting into two classes: (1) the sun, which is very hot and emits great amounts of energy at a range of short wavelengths, and (2) Earth and everything on its surface and in its atmosphere, which are much cooler and emit much less energy and at a range of much longer wavelengths. Within the range of wavelengths emitted by the sun—the solar spectrum—there is a small portion that stimulates our eyes and that we sense as light. The shortest of these we sense as blue light, the longest as red light. So we can divide the solar spectrum into three regions: ultraviolet, visible, and (near) infrared. We do not sense the energy emitted by Earth and its atmosphere in any similar way. But it is sometimes, confusingly, called “infrared” energy, particularly when photographs using special films that are sensitive to these longer wavelengths are involved.

The emission of energy is a cooling process for the body doing the emission, while absorption leads to heating. So, in general, the absorption of solar energy by our planet warms the planet. As the temperature increases, the amount of terrestrial radiation the planet emits increases. In a static universe, planet Earth would reach a constant temperature where the amount of solar energy absorbed would be exactly balanced by the amount emitted to space. However, we do not have a static situation. Fundamentally, the changing position of the sun in the sky gives a changing solar input. Meanwhile changes, natural or anthropogenic, in the atmosphere and on the surface influence the fate of that solar energy. We can think of the planet as constantly striving to achieve this equilibrium temperature. This entry describes the changes that are primarily a response to the changing solar input.

Solar Radiation at the Top of the Atmosphere

The sun emits a tremendous amount of energy; however, because of the distance between Earth and the sun, only a small portion arrives at the top of Earth’s atmosphere. Once allowance is made for the varying distance between Earth and

the sun created by the varying geometry of Earth’s orbit, the amount of energy arriving on a surface at right angles to the sun’s rays at the top of the atmosphere is constant—the solar constant. Even that varies depending on the amount of activity—mainly sunspots—on the surface of the sun. However, for most purposes and for periods of a few years, we can take it as constant. Most of the time, it is more useful to consider energy on a horizontal surface. This notion depends on the angle between the surface and the sun, usually expressed as the zenith angle—the angle between the sun and the local vertical. This angle is the same whether we are at the top of the atmosphere or on the surface immediately below it. The greater the angle, the lower the sun is in the sky and the less intense the radiation onto the surface. The angle is determined by astronomical conditions and depends on the time of day, the time of year, and our latitude. These astronomical conditions control the path of the sun across the sky, our day length, and our seasons. However, the time of maximum solar radiation input—the summer solstice for the Northern Hemisphere—is not the time of maximum temperature on Earth’s surface. Energy has to be transferred down through the atmosphere to the surface, which itself has to respond to the changed conditions, before that maximum can be reached. That process commonly takes several weeks or, in the case of the ocean, several months.

Transmission of Solar Radiation Through the Atmosphere

As solar radiation passes through the atmosphere, it can be absorbed or scattered by the gases of the atmosphere. Absorption amounts are small except in the ultraviolet, where ozone is an important absorber. Some absorption by clouds and pollution is possible, but overall, there is relatively little heating of the atmosphere by direct absorption of solar radiation.

Scattering is much more important. Air molecules scatter the incoming radiation in all directions. This process, known as Rayleigh scattering, is much more effective for short wavelengths than for longer ones, preferentially scattering downward the energy we see as the blue sky light. Rarely

is the atmosphere composed only of dry air molecules. Commonly, there are bigger, but still microscopically small, water droplets present. These are involved in Mie scattering, where most of the energy is scattered in the forward directions, with all the visible wavelengths being scattered more or less equally. As a consequence, while the dry desert air gives deep blue skies and crisp vistas over long distances, a more humid region produces paler skies and more hazy panoramas.

Aiding the Mie scatter process are many other naturally occurring atmospheric particles, ranging from windblown dust to tree pollen. In addition, particles resulting from human industrial and agricultural activity are now also a common constituent of the atmosphere and enhance Mie scattering.

The water droplets that make up clouds also scatter solar radiation. Although a towering cumulus cloud may reflect the radiation downward off its sides, most clouds tend to reflect the incoming energy back to space. So less radiation reaches the surface of the Earth, there is less absorption and heating, and cloudy days tend to be cooler than sunny days.

Radiation at the Surface of the Earth

On average, about 50% of the solar radiation at the top of the atmosphere reaches the surface, either as sky light or as the direct beam of the sun. Some of this incident light is reflected, the ratio of reflected to incident light being the albedo. The albedo is dependent on the type of surface. Snow and ice tend to reflect almost all the energy that falls on them and thus have a high albedo, absorb little energy, and are slow to heat. Water has a low albedo, except at large zenith angles, and serves as a tremendous storehouse for energy. Most land surfaces have intermediate albedo values.

The absorption of solar energy, by whatever type of surface, heats the planet, thus increasing the temperature and the amount of terrestrial radiation that is emitted upward into the atmosphere. However, the solar energy absorption plays three other roles that influence the surface temperature, the terrestrial radiation emission, and the climate of the Earth. First, there is a flow of energy into or out of the land or water underlying the absorbing

surface. This influx provides a small amount of surface cooling in summer and heating in winter, but annually the downward and upward flows are approximately equal. The second process, the transfer of energy between the surface and the atmosphere by heat conduction and convection, called the sensible heat flow, can also operate in either direction. However, upward transfer dominates throughout the year. Finally, the movement of energy by evaporation and condensation processes can also be two-way, but upward motion again dominates.

These three processes, acting in response to the variable incoming solar radiation and in association with the outgoing terrestrial radiation, control our surface temperatures and their variation over space and time. Here, we need only say that the amount of terrestrial radiation leaving the surface of the Earth, being a function of the surface temperature, also varies with space and time and that, since surface temperatures never fall to absolute zero, there is a continuous, 24-hour-per-day, emission of terrestrial radiation.

Geographical Aspects of Solar Radiation

In the previous sections, we have treated solar radiation entirely as an energetic process, of prime interest within geography as the creator of weather and climate. But it has other roles to play, particularly when we consider the wavelengths of the visible portion of the spectrum. For example, the generalized view of surface albedo is adequate when considering atmospheric energetics, but the actual albedo varies greatly with wavelength. Grass reflects very strongly radiation with wavelengths corresponding to green light but absorbs strongly at some longer wavelengths. The consequence is that grass appears green to us, while it can use the absorbed photons at specific energy levels in the process of photosynthesis.

More generally, the dependence of the various scattering processes on the atmospheric composition, which itself is variable both regionally and locally, influences the quality of light at any place. And that often has a profound influence on the sense of place—an important component of many geographic discourses.

Terrestrial Radiation in the Atmosphere

The terrestrial radiation emitted by the surface of the Earth involves a broad range of wavelengths. Most of the naturally occurring atmospheric gases, particularly nitrogen and oxygen, allow transmission through the depth of the atmosphere into space. However, two relatively abundant naturally occurring gases, water vapor and carbon dioxide, absorb strongly at selected wavelengths, while a few trace gases absorb in a minor way. The general result is a two-part view of terrestrial radiation transmission through a clear atmosphere. At one set of wavelengths, known as the atmospheric window, the radiation passes unimpeded into space. At the other wavelengths, outgoing radiation is absorbed. The absorption leads to heating. This heating is combined with that arising from the latent heat release associated with cloud condensation and with that caused by the sensible heat flow from the surface. This combination not only heats all the atmospheric gases but also stimulates the emission of terrestrial radiation from those same gases that absorb that energy. This radiation is emitted in all directions but can be considered for convenience as both up to space and down to the surface. The former is lost to us, the latter is absorbed at the surface and contributes to the heating there. Ultimately, it stimulates more radiation emission, so that apparently circular radiation flow is continuously maintained.

This description implies that all the radiating gases are at the same level in the atmosphere and at the same temperature. This is by no means the case. Although carbon dioxide is commonly well mixed, water vapor is likely to occur in various discrete layers and in discrete regions. So in practice, there are vertical exchanges between the layers as well as horizontal interchanges between regions. The processes are further modified when clouds are present. The water droplets in the clouds tend to absorb at all terrestrial wavelengths, and the atmospheric window is “closed.” Energy that would normally have gone out through that window is absorbed, and at least a part of it is reradiated to the surface. To some extent, more radiation is also emitted from the cloud tops and out to space. But these tops are considerably cooler than the bottoms, so less

energy is emitted. The result is that cloudy conditions allow less heat energy to escape into space, more to return to the surface. The general observation that cloudy nights tend to be warmer than clear ones is a direct consequence of this process.

The Global Energy Budget

On a long-term basis, the amount of energy emitted by the planet and sent to space should roughly balance the amount of solar radiation absorbed by the planet; otherwise the energy content of the planet changes. This change in turn leads to changes in temperature and, potentially, to all aspects of the climate. A short-term balance is unlikely to occur because of the ever-changing energy input from the sun, the natural changes within our planet, and the time required to accomplish the complex interactions sketched above. Over the lifetime of the Earth, there has been a rough balance between the radiation absorbed and emitted, and the climate has tended to fluctuate around a global temperature not too far above freezing. But there have always been fluctuations, and the climate has never been constant.

Relatively recent actions by humans are influencing all the components of the radiation streams. Particulate matter is influencing the transmission of solar radiation. Changes on the surface are influencing the relationships between sensible and latent heat flows and terrestrial radiation emission, while changes in the atmospheric composition are modifying the interaction of terrestrial radiation with the atmosphere. The first two are currently primarily local or regional in scope, but the last is a global effect. Consequently, most attention has been paid to changes in atmospheric composition. The increased concentrations of carbon dioxide and some trace gases, which are transparent to solar radiation but absorb terrestrial radiation, lead to a worldwide modification of the balance between incoming solar radiation and outgoing terrestrial radiation.

RADICAL GEOGRAPHY

Radical geography is not a coherent epistemology, methodology, or area of research, but rather, it represents a shift by academics and scholars from seeking to represent the world toward producing one where social and spatial inequalities are eliminated. It emerged in the late 1960s and early 1970s as a reaction to events both in the world and within the discipline of geography itself. First, it was a reaction to the civil rights movement in the United States, the Vietnam War and the politics of imperialism, the deepening awareness of poverty within inner cities, and other monumental changes occurring throughout the world. Second, radical geography was a reaction against the positivist epistemology and its reliance on empiricism to understand present realities, which dominated the discipline in the 1950s and 1960s. Radical geographers actively questioned mainstream geography's relevance to everyday social life. Together, these factors provided the impetus for geographers to engage in new areas of research, both thematically and theoretically.

Origins of Radical Geography

Three developments were critical in ushering in this new geographical perspective: (1) the establishment of the Detroit Geographical Expedition and Institute in 1968, (2) the founding of *Antipode: A Radical Journal of Geography* (1969), and (3) the publication of David Harvey's *Social Justice and the City* (1973). The Detroit Geographical Expedition

and Institute (DGEI), created by the geographer William Bunge and local community activists, sought to expand both the accessibility of geographic knowledge and the process of knowledge production to poor, largely minority communities in Detroit. It incorporated these communities in all parts of the knowledge production: the identification of the research problem, fieldwork, the analysis, and its dissemination. Consequently, it broke down traditional barriers between researcher/researched and expert/activist. *Antipode* was established in 1969 to provide a forum for scholars and activists to publish materials addressing spatial and social injustices, scholarship frequently rejected from other geographical journals. Early work in *Antipode* commonly documented racial and economic inequalities, examined economic development and natural resources, and analyzed the role of colonialism and imperialism within the world political-economic system. All these issues were at the forefront of the social movement activism across the globe but received relatively little attention in many Anglo-American geography departments and mainstream journals at the time. While early *Antipode* articles drew attention to the uneven development occurring at all spatial scales, it was Harvey's work that shifted the focus from simply describing these processes to explaining them. *Social Justice in the City* chronicles Harvey's intellectual shift from positivist, empirical, quantitative research to his engagement with Marxist political economy. Central to Harvey's contribution was moving geography beyond describing areal differentiation, or modeling locations to maximize efficiency for a diverse set of industries, to a radical geography that examines the spaces produced by the capitalist economic system while interrogating the internal dynamics and contradictions within that system that make social and spatial unevenness necessary. With the work of Harvey, radical geography of the 1970s and 1980s took on a resolutely Marxist identity.

Radical geography rooted in Marxist political economy provided a number of significant contributions to the discipline during this time. In 1982, Harvey's *Limits to Capital* was published. In it, Harvey spatializes Marx's historical materialism and demonstrates how capital accumulation relies on the appropriation of space through a series of "spatial fixes." In understanding

capitalism, Harvey offers historical-geographical materialism as a stronger method for both tracing the origins of contemporary capitalist relations and suggesting its possible futures. Harvey's theorizing was crucial to the development of many subsequent works that expanded his theory and method to other spaces and social relations. In 1984, Neil Smith published a widely influential volume, *Uneven Development*. In it, Smith uses a historical-geographical materialist approach to trace the production of "nature," what he refers to as second nature. In addition, he outlines the creation of surplus value within urban land markets. Smith's examination of nature is significant as one of the first efforts at theorizing nature within radical geography. Doreen Massey also used Harvey's work in her book *Spatial Divisions of Labor: Social Structures and the Geography of Production* (1984), which provided a framework for examining the concentration of particular industries and labor in specific locales. These works and others further solidified the linkages between radical geography and Marxist political economy.

The Feminist Critique

By the end of the 1980s, critiques of radical geography's Marxist foundation were increasingly common. One avenue of critique emerged from a growing body of feminist geography. Feminist geography's development was aligned closely, both temporally and socially, with radical geography. Many early feminist geographers used Marxist theoretical frameworks and were active in radical geography debates and scholarship. However, they also documented significant flaws in early Marxist radical geography. Feminist geographers illuminated radical geography's conception of a world without women by focusing on solely masculinist social relations. Its focus on production and class relations often overlooked the critical aspect of social reproduction, vital in the reproduction of the broader capitalist economy. In addition, socialist feminists argued that the abstract nature of Marxist categories often obscured the role of women within the capitalist economy. Furthermore, feminist geographers suggested that Marxist

radical geography ignored the numerous examples of noncapitalist economies. Besides advocating for different types of radical geography within a predominately Marxist framework, feminist geographers were also at the forefront of another challenge to radical geography. This challenge went beyond the objects of analysis and instead focused on the epistemology and ontology of radical geography itself.

Postmodern and Poststructural Influences

In the late 1980s and 1990s, interventions from poststructural and postmodern theory complicated radical geography's linkage with Marxism. At its heart, postmodern and poststructural critiques questioned the two foundations of earlier radical geography scholarship. The first denounced the decisively modernist vision of Marxist radical geography that suggested the possibility of producing a more socially just world through the attainment of knowledge of the "real world." These critiques owe their intellectual genealogy to the work of Jacques Derrida on linguistics and literary critiques. Poststructural and postmodern theorists argued that language and texts interact with both the producers of knowledge, texts, and landscapes as well as those who encounter them. In this way, knowledge and space are constructed through a process of intertextuality—the interplay between the producers of knowledge, the receivers, and the context within which that interaction occurs. Second, postmodern and poststructuralist theorists eschewed grand metanarratives, such as the role of capitalism, in structuring social life. The belief that social life is created through a host of different relations and contexts is the crux of this critique. Through the work of poststructural and postmodern geographers such as Edward Soja and Michael Dear, as well as the work of feminists such as J. K. Gibson-Graham, the meaning of radical geography began to become increasingly diversified from its earlier Marxist roots.

Redefinitions of Radical Geography

The destabilization of radical geography's meaning and content in the 1990s fostered an entire

new lexicon among geographers working within leftist political scholarship. Left-wing geographical scholarship, once known as radical geography, became left, critical, Marxist, feminist, poststructural, postmodern, and postcolonial geographies. Radical geography became fractionized across a host of epistemologies, ontologies, methodologies, and themes. This led to a process of internal soul searching regarding the meaning of radical geography. The debate over the meaning of radical geography is diverse, but two distinct themes have reoccurred frequently: (1) the theoretical commonalities within radical geography and (2) how radical geography is practiced (praxis).

Theoretically, several interventions into the meaning of radical geography have emerged. One aspect of this discussion is illustrated in the work of Amin and Thrift (2005). They argue that the growing pluralism within radical geography in the 1990s and 2000s is a strength and should be celebrated. They see in a new pluralist radical, left, or critical geography an opportunity to develop new politics that can contribute to the objectives of the radical project as initially conceived. In addition, they reaffirm the theme introduced by postmodernism that no one overarching theory can offer a holistic view of social relations. Others have sought to reaffirm the materialist bases of early scholarship in radical geography, arguing that it is the best theoretical framework for understanding the extreme inequalities that allow some to live in overwhelming comfort and abundance while others live with a constant struggle for survival. These authors express the significant internal debate regarding radical geography's theoretical foundation.

The practice or *praxis* of radical geography has also received considerable attention among geographers in recent years. Numerous radical geographers have interrogated the question of where and how to practice radical geography. What began as an intervention into the disconnect between radical geography research and theory and its "on the ground," "out there" activism quickly expanded. In its early manifestation, this debate addressed the relevance of radical scholarship to activists, communities, and policy. Efforts were made to encourage or cajole radical geographers to engage with the

world outside the academy, both theoretically and in practice, and to critically examine the contributions made by radical geographical research to radical politics in practice. However, others have questioned the necessity of radical scholarship engaging in activism in the community. Recently, Mitchell (2004) suggests that radical geographers can provide activists with the resources and tools necessary to create a radical vision of social justice and equality by focusing on doing good analysis itself. This vision of radical geography contests the notion that radical geography must engage in activist practice outside the academy and highlights the resources within the academy that make radical geographers uniquely positioned to contribute to activism through their scholarship: financial resources, time, the safety of tenure, and the power of good theory. This line of radical geographic praxis is currently at work in the recent Right to the City movements, which rely on the work of Lefebvre and Mitchell.

In recent times, geographers have expanded Mitchell's notion of doing good work within the academy. There has been a growing body of work pushing radical geographers to put as much energy into a radical pedagogy and teaching activities as they might into activism outside the academy or in radical research. In addition, emphasis has been placed on radical geographical work seeking to actively change the working conditions of the labor force closest to radical geographers: the university. This has led to a vibrant discussion at conferences and in journals of the corporatization of the academy and the working condition of both academic and nonacademic labor. In addition, discussion among radical geographers has also focused on the process of publication and the professionalization of radical geography's first journal, *Antipode*.

scale. Radiometric correction is one of several corrections performed on satellite image data prior to the retrieval of land, atmosphere, and ocean information. These preprocessing procedures are essential for ensuring high-quality information from remote sensors. Radiometric correction ensures that measurements and methods yield self-consistent and accurate geophysical and biophysical data, even though the measurements are made with a variety of different satellite sensors under different observational conditions and the parameter retrieval methodologies vary.

Overview

Radiometric correction is important for the successful conversion of digital image data from satellites to calibrated surface quantities in the Earth science context. Figure 1 shows the many possible paths that photons take from their source—the sun—to the entrance aperture of the satellite sensor imaging Earth, with five main pathways and associated interactions.

Radiometric corrections of optical sensor data consider sensor radiometric calibration, surface reflectance retrieval, spectral characterization, and georadiometric effects on image radiometry. By convention, raw image data and calibrated radiances at the top of the atmosphere (TOA) are referred to as Level 0 and Level 1 data, respectively. For analysis in quantitative applications, Level 2 data, consisting of radiometrically calibrated and geolocated physical variables such as surface reflectance, emittance, temperature, and so on, are preferred or required. Still higher data product levels consist of information products that are integrations, temporal aggregates, or spatial aggregates of lower-level data.

Sensor Radiometric Calibration

Sensor radiometric calibration is a broad and complex field that imposes the greatest limitations on quantitative applications of remote sensing. The methods and instrumentation involved can be grouped into three domains: (1) on the ground prior to launch, (2) onboard the spacecraft post-launch (including reference to lamp sources and/or solar illumination or lunar illumination), and

RADIOMETRIC CORRECTION

Radiometric correction is important to ensure that terrestrial variables retrieved from optical satellite sensor systems are calibrated to a common physical

(3) vicarious approaches using Earth scenes imaged in flight.

Surface Reflectance Retrieval

In many applications, surface reflectance is the geophysical variable of particular interest in the

solar reflective part of the electromagnetic spectrum. However, scattering and absorption due to gas molecules and aerosols in the atmosphere modify surface reflectance propagated through the atmosphere to the satellite sensor. Given that the optical properties of Earth's atmosphere are not uniform spatially or temporally, image

corrections for these effects in the solar-reflective spectral bands are needed on a case-by-case basis to put satellite data on the same radiometric scale for investigations intended to monitor terrestrial surfaces over time and space.

Spectral Characterization

Spectral bands are designed for specific applications, and data products are susceptible to post-launch variations in spectral bandpasses or to spectral band differences between different sensors used in a given applications algorithm or model. In practice, there is little that users can do to take into account the changes in the spectral band performance. However, even when spectral bands perform as designed, users should be aware that similar information products derived from different sensors with analogous spectral bands that do not match exactly are not necessarily directly comparable.

RADIOMETRIC NORMALIZATION

Remote sensing applications often use image time series or mosaics of various images or image parts. *Radiometric normalization* generally refers to empirically reducing the differences between images in time series or mosaics related

to differences in the image acquisition time or date. These differences can affect the accuracy of image interpretation. In satellite-based optical remote sensing, these differences include differing atmospheric conditions, target illumination, sensor calibration, or surface phenology. Radiometric normalization is applied both to images that have undergone atmospheric correction and to those that have not.

Image radiometric normalization is warranted when

1. the spectral signatures from one image will classify other images without other normalization,
2. the particular approach to time-series analysis requires that the radiometric differences between images be minimal, or
3. a single linear model that does not account for image date will classify an image mosaic.

Radiometric normalization is mathematically superfluous when change detection consists of stacking images through time and then simultaneously classifying them empirically, as with a maximum-likelihood classification. Radiometric normalization may also be unnecessary when using machine-learning models, to classify an image mosaic, if the reference data for the classification model represent all image dates.

To radiometrically normalize images to a reference image or to each other, calibration models are estimated from pixels in the images and then applied to the imagery. Normalization models estimated from linear regression between manually selected, spectrally stable features, such as human-made structures, are unreliable if the goal is to normalize differences in surface phenology. Models estimated from all overlapping pixels, with linear regression, histogram matching, or regression tree normalization, are more stable. When pixels that have not undergone real change dominate images, removing changed pixels before estimating the model is statistically unnecessary. Regression tree normalization matches vegetation phenology more closely than histogram matching, and histogram matching may yield better results than linear

regression. Localized approaches estimate a separate model for each pixel based on overlapping pixels within a surrounding window. Of all these approaches, only regression tree normalization and localized approaches can normalize nonlinear image differences in vegetation phenology, but these approaches can also result in some loss of image detail.

RADIOMETRIC RESOLUTION

Radiometric resolution is the radio-frequency sensitivity of a remote sensing platform. Usually captured from airplanes and space-based satellites, remotely sensed data provide a uniform view of geographic space. This view of Earth can extend beyond the visible range of wavelengths.

Remote sensors have four resolutions: spatial, temporal, spectral, and radiometric. Commonly referred to as the pixel bit depth of a sensor, radiometric resolution is the sensitivity to reflected radiation across the spectral resolution of the sensor. Consumer digital cameras, for instance, detect visible spectrum light using a CCD or CMOS sensor with 8 bits of radiometric resolution for red, green, and blue bands. This translates to 256 possible shades of each color band for an aggregate 24 bits of radiometric resolution, resulting in more than 16 million different colors for each pixel. The Multispectral Scanner (MSS) on Landsats 1–3 had a radiometric resolution of 6 bits for 64 levels for each of the four bands: red, green, blue, and near-infrared. The Landsat Data Continuity Mission (LDCM) proposal specifies a new array of sensors with 8 bits of radiometric resolution for each of the nine bands of radiation. Radiometric resolution presents a trade-off as with spatial resolution due to data collection and transmission limitations. Increasing the radiometric resolution directly increases the volume of data transmitted. Furthermore, increasing the radiometric resolution has been shown to mostly increase the noise versus the desired signal.

RAILROADS AND GEOGRAPHY

One of the central technologies of the Industrial Revolution, and perhaps the most important child of the steam engine, was the railroad, which, along with steamships, played a central role in giving birth to radically new geographies of social and economic life. Railroads were central to the rise of modern capitalism and the opening up of continental interiors through rapid, cheap, and dependable transportation and were thus the most explicit symbol of the vast wave of time-space compression unleashed throughout the 19th century. In addition to their ability to shuttle people, railroads could move heavy loads over long overland stretches, but not in areas with too steep a grade, reducing land transport costs by as much as 95%.

This entry first reviews the evolution of the railroad in Europe and the United States, as railroad lines contributed to the growth of capital cities, expanded markets, and increased the accessibility of previously remote areas. The entry then explores the impacts of rail transportation not only on the experience of travel but also on national and international commerce.

Historical Development

Britain

British railroads, the world's first, began with the Penydarren Tramroad in Wales in 1804, although it did not rely on steam power. In 1814, George Stephenson unveiled the first steam locomotive, and the British system expanded rapidly, including the Stockton and Darlington Railway

in 1825, one of a series of famous Newcastle railways. In 1830, the first interurban railroad connected Liverpool and Manchester. Early railroads achieved speeds between 20 and 30 mph (miles per hour), or three times that achieved by stagecoaches; later ones achieved speeds of up to 70 or 80 mph. By 1838, the London to Birmingham route opened to immediate success, reducing the time needed to travel the 112 mi. (miles) in between from 12.5 to 5.5 hrs. (hours). Other travel times fell accordingly: London to York, for example, took 96 hrs. to walk in 1754, 36 hrs. by stagecoach in 1776, and 20 hrs. by railroad in 1830.

During a period of intense, widespread, and rapid urbanization, railroads soon became the dominant sign of the Industrial Revolution in much the same way as the Internet came to symbolize postmodern capitalism. The enormous costs of constructing and maintaining such networks, however, required high volumes of traffic to amortize expenses over numerous clients. Fortunately, the velocities of the new system were popular: British passengers increased from 5.4 million in 1838 to 170 million in 1862. Originally, British railroads deployed the 4-foot, 8-inch gauge of the coal mines. The integration of wider markets, however, required standardized tracks, which led other countries eventually to adopt the British standard. The standardization of different European rail gauges was finally accomplished with the International Railway Conference of 1882, which took more than a decade to unfold.

Russia

In Russia, railroads helped forestall a decline into Third World country status. With the opening of the Moscow-to-St. Petersburg line in 1851, Russia's railroads zoomed from 700 total mi. in 1860 to 12,500 mi. in 1878, to 21,000 mi. in 1894, and 36,000 mi. in 1900. The first leg of the Trans-Siberian railroad opened in 1903, stretching 6,000 mi. from Moscow to Vladivostok; by reducing journey times between Europe and Asian Russia from months to days, it brought the vast resources of Siberia into the tsarist spatial division of labor. Within a decade, 2.5 million Russian settlers were living in northeast Asia. The Trans-Siberian railroad was therefore central in making

Russia a formidable land power, a point important to the geopolitics of Halford Mackinder.

Japan

As Japan moved rapidly from a feudal to a capitalist society in the late 19th century, its railroad network sutured the country's diverse local economies into a nationally integrated system. The Japanese rail system first linked Tokyo and Yokohama in 1872. Other lines reinforced the centrality of large urban centers, including Osaka.

Italy

In Italy, the railroad became an instrument of national unification—a process achieved in the face of the growing economic and political ascendancy of the North at the expense of the peninsula's southern districts. Transportation integration in Italy came late, however, with the Florence-to-Rome line completed only in 1933.

France

The French railroad system, centered, naturally, on Paris, soon made the capital accessible to people throughout the nation; equally important, it made the French peripheral territories accessible to Parisian capitalists (Figure 1). During the 19th century, the French rail system generated a condensed geography in which all cities approached Paris, and vice versa, deeply reinforcing the centrality of the capital. Lines ending at different stations in Paris reflected the dominant conception that railroads did not go *through* Paris, they simply ended there.

This pattern in several different countries reflects the profoundly uneven national geographies of industrialization facilitated by the railroad—that is, the rising prominence of cores of capital accumulation at the center of national transport systems. Similarly, the British railroad heavily favored London and brought most of the island within a 10-hr. traveling time from the capital.

The United States

The American rail experience paralleled that of Britain in generating a transport surface increasingly ubiquitous across national space.

Beginning with the first line in Quincy, Massachusetts, in 1826, Boston became the world's first rail hub, with three radial lines. It took only 43 years to move from the first rail line in 1826 to the famous transcontinental connection of the Union Pacific and Central Pacific lines at Promontory Point, Utah, on May 10, 1869, connecting the multitude of farms, towns, and cities stretched across North America.

American railroads had inestimably profound impacts on the country's social, urban, and economic geography, opening the coal mining districts of Appalachia and the meat and grain belt of the Midwest alike. The time-space effects of the railroad system were highly uneven geographically, integrating the northeast and the Midwest far more than they did the northeast and the South. Just as there were significant differences in the urban and regional impacts of railroads between Britain and France, so too in the United States did the consequences of railroads vary. Because American labor was relatively expensive and land was cheap—the exact opposite of Europe—railroads in the United States tended to curve much more around hills and valleys. American railroads were instrumental in opening up the vast wilderness of the continental interior, and train travelers across the prairies compared trains with ships on land. In essence, this wave of time-space compression turned the Great Plains and Prairies into a giant agricultural bread basket, a process that established Chicago as the premier center of capital accumulation in the continental interior. The completion of national rail networks also facilitated the specialization of individual cities, which often realized comparative advantages based on local resources, strategic locations, and contingent pools of labor skills. Chicago witnessed particularly explosive growth in the 1840s due to its location as a transportation hub. The huge wave of time-space compression that railroads unfolded across North America catapulted Chicago from a tiny backwater to the world's first commodity market and futures exchange center. The accelerated velocity and improved reliability of shipments brought the Midwest steadily into the orbit of the eastern capital. Shortly after the Civil War, the Rocky Mountains and the west coast were incorporated into the American space economy,

Figure 1 The evolving French railroad system. In France, railroads greatly enhanced the centrality of Paris.

Source: Author.

which soon thereafter became the largest in the world, surpassing Britain in the 1890s. The gulf between the east and the west coasts was finally breached by the telegraph wires in 1861 and railroads in 1869. Throughout the late 19th century, the U.S. railroad network formed a dense web over the eastern half of the country (Figure 2), a system that represented 40% of the

world's railroad capacity. The railroads adopted the telegraph enthusiastically, to send news of construction, accidents, and changes in schedule. Railroads were particularly enthused because the telegraph allowed information about train position to be relayed accurately, thus improving safety and omitting the need for double tracks.

The city of Chicago has been a major railway hub for more than a century. In October 1848, the steam locomotive *The Pioneer* began carrying construction supplies and workers over the Galena & Chicago Union Railroad, inaugurating rail service to the city. By the 1880s, Chicago was served by nearly 20 long-distance rail carriers and several switching and terminal companies. Today, it remains the largest railroad hub in the United States. Shown above are tracks leading south from Chicago's Union Station to Amtrak's Chicago Yard and 14th Street Shop and control tower, about 1 mi. south of Chicago's central business district. On the right are additional tracks to stage Metra commuter trains for rush-hour runs, with Metra's own shops just outside the photo. The viaduct crossing the tracks is Roosevelt Road, and the trees across the river are growing on rail yards abandoned as industries using rail have moved further from the central core and rail passenger service has largely been replaced by air and car travel.

Impact of Railroads on the Experience of Travel

Railroads also dramatically changed the subjective experience of travel. Accelerated speeds transformed the dominant former means of travel, horse-drawn carriages, into something slow, whereas previously it had been the quickest way to go. Moreover, the older, animal-driven technologies, Schivelbusch (1977) maintains, preserved a "mimetic relationship" to the space traversed, permitting travelers to perceive space intimately. With

the introduction of steam power, however, animal-based transportation was rendered hopelessly anachronistic, and the close relationship between traveler and the traveled space was uncoupled. Unlike animal transportation, which was irregular and bumpy (horses' hooves needed traction), railroads moved smoothly at a constant rate, and the mechanism of propulsion was largely invisible, incomprehensible, or misunderstood by most travelers. Many early descriptions of railroads liken them to projectiles or rockets. The sheer speed of rail travel appeared unnatural to many early riders

U.S. Railroad System in 1860 and 1890 over modern state boundaries

Figure 2 Growth of the U.S. railroad network. Transcontinental railroads facilitated the formation of national markets and large oligopolies in the United States.

Source: Author.

and prevented them from close observation of their surroundings. Railroads ushered in new perceptual landscapes, divorcing travelers' bodies from their traditional experiential linkage to external space, forcing them to construct new forms of consciousness to interpret the landscape as it whizzed by.

Among other things, this new phenomenology of movement entailed a much greater ability to deflect irrelevant stimuli. Unable to hear sounds in the places they passed by and unable to look ahead, passengers confronted a rapidly passing blur that substituted for the foreground. Slow, careful views

of nearby objects were replaced by rapid, superficial scans of distant ones in the background, making passengers feel disembodied from the places through which they flew, leaving them with a fleeting, impressionistic understanding of their surroundings. Medical doctors of the time associated the rail experience with the new health problems of eye strain and stress. Thus, despite the economic gains unleashed by industrial time-space compression, the process also entailed experiential losses: The quantitative size of spaces traveled through expanded greatly, but the qualitative appreciation of the experience declined.

Railroads also fostered an outlook that emphasized precision rather than the old “inexact” habits. With the railroad, speed became an established principle of public life and a synonym for progress. Punctuality became increasingly regarded as socially normative: A few minutes meant the difference between catching or missing a train. The new environment democratized access to velocity: For example, women were able to travel alone without a male escort, an unheard-of phenomenon prior to the railroad. The psychic transformation wrought by rail travel carried over even into the simple process of embarking or disembarking.

Within cities, too, railroads were potent in restructuring urban land markets, initiating rounds of change in the urban rent surface that amplified some land values and eroded others. Railroads simultaneously intruded on older cities, destroying the traditional fabric of urban space and giving rise to new ones. As the commodification of urban space intensified, specialized districts of production and social reproduction materialized apace within divisions of labor that became spatially extended and more integrated. Outside urban areas, railroads allowed the rhythms of the city to penetrate the countryside. By making distant lands accessible, railroads dramatically extended the rent surfaces of urban areas, commodifying land in hitherto inaccessible regions and encouraging farmers, settlers, and planters to assault distant, relatively untouched ecosystems.

Economic Effects of Rail Transportation

Far from constituting some mythical process of “free market” expansion, the growth of the railroads was actively abetted by the state, including

the land grants introduced in 1850. In the United States, the Interstate Commerce Act of 1887 standardized rail gauges. Thus, rather than unfettered supply and demand, the state intervened actively to facilitate the time-space compression of industrial capitalism. This process effectively allowed politically powerful commercial interests located on the east coast to gain easy access to the resources and markets situated in the Midwest and west.

One of the most significant long-term impacts of the relational geographies that the railroad fostered was the rise of dramatically expanded markets on the scale of the nation-state. Prior to the Industrial Revolution, with markets highly localized and self-sufficient, long-distance trade was comparatively rare. In 1817, for example, it took 52 days to ship goods from Cincinnati to New York by river using wagons. Between 1830 and 1857, most of the country was within a few days’ travel of New York City. Interregional commerce tended to be export oriented and controlled by merchants in large east coast cities. As long as production and consumption were confined to regional markets, goods retained the identity of their origin. Railroads, however, allowed large-scale commercial providers to lower costs, increase productivity, and raise profits while using the new technologies to conquer space in ever more effective ways, expanding their operations by diminishing geographic barriers. Within the new, larger markets, prices tended to equalize quickly. This process generated “economies of speed” in which maximization of throughput set the stage for the emerging Fordist regime of production. All this was central to the transition from small, isolated, and localized markets to larger national ones, a new geographic formation that was highly conducive to the rise of larger, capital-intensive, vertically integrated, multi-establishment firms and oligopolies as companies internalized their commodity chains.

Other Social Impacts

Railroads had other social impacts as well, including on the media. For example, there were hardly any mass-circulation magazines prior to 1850. Their emergence in the United States, based on the economies of scale offered by large markets, was made possible by the completion

of the transcontinental railroads in 1869 and the Postal Act of 1879, which allowed for cheap distribution of commercial material. Another consequence of railroads was in the expanding geographies of mass tourism. Prior to the railroad, for example, high transport costs kept isolated areas far from the reach of the urban masses and were often the recreational preserves of wealthy elites. The railroad made the Grand Tour of Europe—a *de rigueur* rite of passage for the educated *petit bourgeoisie* on both sides of the Atlantic—obsolete as hotels, newspapers, and the new technologies of transportation all made the process of mass tourism more comfortable, safe, and reliable, facilitating the mass movement of people across and within national boundaries and encouraging widespread appreciation of cultural differences. In the 1840s, Thomas Cooke began to organize cheap train trips to the coasts of Britain for working-class families. Railroads in the 19th century and airplanes in the 20th century opened up exotic places to the middle classes, who frequently took them over, often destroying the very uniqueness that made them attractive in the first place. Places, like goods, became standardized and commodified, locked into an increasingly national, then global, system of production, circulation, and consumption.

In European colonies, too, the railroad unleashed enormous impacts, although in contrast to the colonial countries, these were generally designed to favor the broader process of exploitation. In India, for example, the British railroads began in 1853 but rose rapidly following the Sepoy Mutiny of 1857 to become the largest railroad system in the colonial world, primarily to facilitate cotton and jute exports to the textile mills at home and troop movement to control the native population. By 1870, the British had laid 4,500 mi. of track, which by 1936 expanded to 43,000 mi.—the fourth largest network in the world. Investors in Indian railroads were guaranteed a 5% annual rate of return by the British government. Similarly, in Southern Africa, rail lines were central to Cecil Rhodes's pacification program. By the 1920s, the vast majority of the population of the economically developed world lived within 10 mi. of the "civilizing rails," blanketed by a network that suggested near-ubiquity

of access. Conversely, relatively few people in Asia, Africa, or Latin America did so.

Railroads and the Standardization of Time

One of the most explicit repercussions of railroads was the standardization of time. England, the first to build railroads, was also the first to adopt a standard railroad time: In 1847, the British Railway Clearing House suggested that all rail stations adopt Greenwich Mean Time (GMT), the special preserve of the Royal Observatory located there, which was founded in 1675. Because Greenwich time was distributed via the telegraph wires, it was long known as "railway time." By 1855, GMT became the legal standard throughout the country.

In the United States, given its vastly greater size, a somewhat different set of conditions prevailed. In 1870, the United States still had roughly 200 local times and 80 different railroad times, generating great confusion among railroad passengers and companies. In that year, Charles Dowd suggested four time zones based on four standard meridians, the easternmost of which passed through the U.S. Naval Observatory in Washington, D.C. Uniform time was voluntarily adopted on November 18, 1883, the "day of two noons" because clocks had to be set back to generate a national railway time. By adopting Greenwich as the Prime Meridian, the United States and Canada provided a model for the international adoption of the same innovation.

Railroads in the 20th Century

In the 20th century, railroads faced growing competition from automobiles and trucks for the movement of people and goods, respectively, and their significance declined accordingly. Currently, though freight trains still play an important role in shuttling commodities cheaply over long distances, especially with the introduction of containerization and double stacking, the aggregate impacts are considerably lower than they were during the golden era of the late 19th century. An important development was high-speed trains, which form a key part of interurban transit systems in densely populated, economically advanced countries with strong state backing (but not the

United States), including the Japanese *Shinkansen* (“bullet trains”); France’s *Train à Grande Vitesse* (“high-speed train,” TGV), which cover the 275 mi. from Paris to Lyon in just 2 hrs., operating at roughly 180 mph; Germany’s *Neubaustrecke* (“newly constructed routes,” NBS); Spain’s *Alta Velocidad Española* (“Spanish high-speed train,” AVE); and the British Inter-City 125, which brought all of England within 3 hrs. of London. With speeds of up to 300 kph (kilometers per hour), such systems are competitive with air travel for distances of up to 500 km (kilometers). The driving force behind these systems has been primarily economic, particularly the need to shuttle well-paid executives between corporate offices. Not surprisingly, the heavy European emphasis on such systems was tied to the creation of a single internal market under the European Union. High-speed trains invariably shrank the relative spaces between large cities by skipping over smaller, intermediate nodes.

RAISZ, ERWIN (1893–1968)

Erwin Raisz played a key role in the professionalization of cartography within the discipline of geography, and deservedly he is ranked with early luminaries in the field such as John Paul Goode, Arthur Robinson, and Richard Harrison. His major contribution was in the area of landscape representation, and beginning at least a decade before World War II, he published literally thousands of maps, both large and small scale, depicting landforms throughout the world. Many were made to illustrate books, and even today his maps often continue to be used as book illustrations. He also authored *General Cartography*, which for decades was the only textbook in the English language on the subject.

The direction of Raisz’s career seemed to have been established at his birth in 1893 in Levoca, a town in today’s Eastern Slovakia. His father, a Hungarian civil engineer, was temporarily stationed there. Raisz has been quoted as saying that as a young child he occasionally carried his father’s surveyor’s rod and peeped into his transit. Following more or less in his father’s footsteps, he studied engineering and architecture at the Royal Polytechnicum in Budapest and received his diploma with honors in 1914. Following military service in World War I, much of it in action, he briefly worked in Hungary, but in 1923, he emigrated to the United States, where he found employment in New York with a map company.

Shortly after his arrival, he entered graduate school at Columbia University’s department of geography, receiving his doctorate in 1929. Raisz’s cartographic skills began to be recognized during his student years at Columbia, not only by his professors, who used his maps to illustrate their research, but also by publishers who needed map illustrations. Raisz’s own students also admired his skill at depicting landforms from contour maps. Raisz would enter the classroom with a roll of Kraft paper, from which he would unroll a long strip and pin it to the blackboard. Then, he would depict the map’s surface with an array of colored chalk and a U.S. Geological Survey (USGS) contour map.

Raisz’s landscape depiction skills led him to gain employment at Harvard’s newly established

Institute of Geographical Exploration, where he remained for 20 years, his employment ending in 1950, when, shortly after the closing of Harvard's department of geography, the benefactor of the Institute withdrew his support. By then, Raisz's reputation as a cartographer was well established, and he carried on his work at home and as a visiting lecturer at universities in Virginia, Florida, and British Columbia. Raisz continued to work until his death in 1968 in Bangkok, Thailand, en route to a meeting of the International Geographic.

RANK-SIZE RULE

The rank-size rule is a mathematical description of the sizes of cities within a given urban hierarchy. It states that the rank of a city with size S relative to the largest city in that hierarchy is proportional to some negative power. It was first proposed by George Kingsley Zipf in 1949. The negative power should be close to 1 in absolute value, which implies that the second largest city is half the size of the largest, the third largest city is one-third the size of the largest, and so on. In cases where this power is greater than 1, it suggests that the second largest city is more than half the size of the largest city, the third largest city is more than one-third the size of the largest city, and so on.

The rank-size rule is commonly expressed as follows:

$$R_i = \alpha S_i^{-\beta}, \quad (1)$$

where R_i is the rank of the i th largest city, S_i is the city's size, and β is the exponent coefficient.

A log transformation can be used to estimate β as follows:

$$\log(R_i) = \alpha - \beta \log(S_i). \quad (2)$$

The rank-size rule has two striking features. One is its excellent empirical fit. Numerous studies have shown that a linear regression of log-rank on log size (as shown in Equation 2) generates an excellent correlation (high R^2 value). For example, Rosen and Resnick (1980) used data from 44 countries and found that R^2 values were above 0.95 for 36 countries, with only Thailand having an R^2 value lower than 0.9. This astonishing regularity led Paul Krugman (1995) to say that the rank size is "a major embarrassment for economic theory: one of the strongest statistical phenomenon we know, lacking any clear basis in theory" (p. 44).

The other striking observation is about the power exponent. For the 44 countries studied by Rosen and Resnick (1980), the estimated coefficient ranges from 0.809 for Morocco to 1.963 for Australia.

Several studies have noted that estimating Equation 2 of the rank-size rule yields an ordinary least squares (OLS) bias through standard errors. The following version corrects for the bias, giving the standard errors of the exponent the form $(2/\bar{n}_i)^{0.5} \hat{\beta}$, where $\bar{n}_i$ is the corresponding subsample size. Instead of Equation 2, they offered the following:

$$\log(R_i - 0.5) = \alpha - \beta \log(S_i). \quad (3)$$

This corrected version is known as the "rank minus half" rule. The estimated coefficients ($\hat{\beta}_s$) are slightly higher for the OLS-bias-corrected model than for the original uncorrected version.

The rank-size rule is remarkably consistent and frequently referenced. Its causes are highly debated, with some suggesting that it is purely a statistical phenomenon. The applications of the rank-size rule are growing and leading to interesting questions.

RATZEL, FRIEDRICH (1844–1904)

Friedrich Ratzel was a famous German geographer, zoologist, and anthropologist. His extensive work on the links between the physical environment and society and the organic nature of the state (*Lebensraum*, meaning “living space”) laid the foundations for geopolitics and political geography.

Apprenticed as an apothecary, it was not until age 21 that Ratzel read zoological studies at Heidelberg University, which introduced him to Darwinism, as interpreted by his then mentor, Ernst Haeckel. After Heidelberg, Ratzel briefly worked as a travel correspondent and was awarded the Iron Cross after enlisting in the Baden Infantry during the Franco-German War (1870). Following the war, he studied with Moritz Wagner at Munich, whose Lamarckian views on species migration later influenced Ratzel's own anthropogeographic works. In 1886, he was awarded a professorship at Leipzig University, a position he held until his death in 1904 following a stroke.

Ratzel's writing was extensive and wide ranging; he was a rare geographer who published both human and physical works. His most notable works are *Anthropogeographie* (Vol. 1, 1882; Vol. 2, 1891) and *Politische Geographie* (1897). *Anthropogeographie* is a two-part study of the relationship between society and the physical environment, with many commentators seeing the first

volume as an application of geography to human history and the second as a description of the geographic distribution of humankind. These works were slow to reach Anglophone geographers, with their eventual dissemination largely credited to Ellen Churchill Semple, an early adopter of the Ratzelian program outside Germany. These works have been the subject of much debate as to their links to environmental determinism and discourses of race. This idea, however, owes more to Semple's interpretation of Ratzel's ideas rather than Ratzel's initial aims of his work.

Politische Geographie considered the state as an organism expanding into space to grow, thus states required *Lebensraum* to grow. This work draws on biogeographical and Lamarckian language relating to evolutionary theory and is considered as part of a wider volume of theory regarding social Darwinism. Karl Haushofer's Geopolitik School (between 1920 and the 1930s) later adopted elements of Ratzel's work, stressing the need for state expansion to create *Grossraum* (“big space”). This idea became politicized and was adopted by the National Socialist (Nazi) movement as justification for its expansionist policies. Ratzel never imagined *Lebensraum* as part of a Nazi agenda—a movement he distanced himself from—instead suggesting that *Grossraum* would be a site of cultural intermixing for the good of the state.

REAL ESTATE, GEOGRAPHY AND

Real estate market analysis is executed using highly sophisticated geospatial analytic procedures, geospatial technology, and geospatial databases. The objective of geospatial real estate market analysis is to improve real estate decisions regarding all kinds of real property. Beneficiaries of real estate geography include individual real estate consumers, individual real estate investors, large Real Estate Investment Trusts (REITs) and pension funds, financial institutions, multibranch retailers, advisory firms, economic development agents, and others holding real estate assets.

Real estate market analysis is the “location, location, location” of real estate. Real estate market analysis is essentially “information arbitrage,” that is, the generation of small but important advantages in useful information about real estate opportunities (Thrall, 2002) and transacting on that knowledge. Geographic information systems technology, geospatial analysis, and geospatial data are core to the acquisition and utilization of information in the real estate market.

Geospatial technologies change real market analysis from a solely financial decision to a holistic one tied to location, submarkets, aggregate markets, and geographic interdependencies. Real estate market analysis is a process that culminates in a decision regarding property, as well as a prediction of future real estate trends across space and time. It involves taking past and current information and assessing current market conditions and predicting future market conditions for specific sites, submarkets, aggregate markets, and the range of other real estate asset categories.

A real estate geographer often proceeds geographically top-down, beginning at a very broad level, such as a nation or state/province, then interpreting geospatial data related to a smaller area, such as a specific county, then identifying submarkets, and last zeroing in on a set of specific sites for comparative evaluation.

Anyone involved in real property markets benefits from and likely currently uses real estate geography. Developers must understand factors such as rent levels, absorption, construction costs, underserved markets (gaps), and the cost

of capital to make intelligent decisions about when, where, and the “go” or “not go” development decision. Those who plan to lease space create geospatial due diligence documentation, including analysis of current market rents and the likely future trajectory of rents; the due diligence informs how much to spend on rent and how long the lease should be. Purchasers, both users and investors, create geospatial due diligence documentation, including an analysis of current market values and the likely future trajectory of market values; the geospatial due diligence is input into the financial analysis, which together informs how much to invest and the expected or desired holding period. The value that a real estate broker has to a buyer or seller is the value of their “information arbitrage.” Brokers need to have real-time access to geospatial information and geospatial analysis of the marketplace to be credible at marketing space and representing tenants. Government officials can benefit from the skills of the real estate geographer to anticipate infrastructure need that results from new development and to coordinate economic development initiatives.

Real estate geographers work with a development team. Financial analysts depend on the business geographer to provide information for the evaluation of the necessary return to investors in order to compensate for risk and opportunity cost. Other team members include those who evaluate the cost to either newly construct or replace the real estate asset within a given geographic submarket. The real estate geographer receives this information and then estimates the tipping points between investment and disinvestment—namely, when to go into the market and when to exit the market.

Geospatial Tests for Successful Real Estate Decisions

To ensure a positive outcome, all real estate decisions must have answers to five geospatial feasibility questions:

1. Does the forecasted supply and demand relationship for the trade area of the property asset indicate success?
2. Is the proposed project the “highest and best” (i.e., most profitable) use of a site?

3. Will the asset perform at levels for the time period necessary to achieve the required return on investment?
4. Considering risk and all other factors, is the expected performance of the proposed project greater than alternative project opportunities at the same or alternative locations?
5. What are the tipping points for profitability, and what conditions can bring about those tipping points?

The real estate geographer's geospatial feasibility model is shown in Figure 1, which shows the interdependence between geospatial market feasibility, geospatial location/site feasibility, and financial feasibility. Omnipresent in the background are the forces of political and social change, at the local to the global geographic scales. Financial feasibility analysis requires qualitative and quantitative data from the other two geospatial feasibilities to be executed. Interdependently, the three geospatially linked feasibilities are fed into the judgmental decision regarding the real estate asset, and this must be done in the context of risk emanating from political and social

Figure 1 The geospatial feasibility model

Source: CCIM 102 *Real Estate Market Analysis*. Chicago: CCIM Press.

change. The geospatial feasibility model shows that business judgment is a process of integrating analyses of market feasibility, location/site feasibility, and financial feasibility. Because the business decision is geographically site specific, the supporting analysis must also be geographically site specific.

Geospatial due diligence documentation required to support the core business decisions to “go,” “not go,” and “modify” in Figure 1 include the following:

- Calculation of the trade area, the submarket, and the aggregate market
- Calculation of existing competitive supply within the relevant geography and relevant time period
- Estimation of future competitive supply known as “the pipeline” within the relevant geography and relevant time period
- Estimation of demand for the particular real estate asset, at the specific location for the current and the relevant future time period
- Estimation of the demand and supply gap for the real estate asset class within the relevant geography over the relevant time period
- Evaluation of risk arising from geopolitical and geosocial issues

If projected demand for the particular type of real estate within the relevant geographic submarket exceeds the total supply, then a gap is identified and a profit opportunity for investors may exist. The real estate geographer's analysis of market feasibility might then indicate support for the proposed development. This dynamic iterative process is shown in Figure 2.

Financial feasibility depends on the magnitude of profit opportunity. Here, the site-specific analysis becomes integrated with national and international financial markets. Also, the profit opportunity is accompanied by a level of risk that diminishes the expected return. Investors must be convinced that they will receive an above “tipping point” expected return. Hence, the financial feasibility component and the geospatial components are necessarily interdependent, each feeding back on the other and each necessary for the business decision. The site-specific development decision is

Figure 2 Dynamic iterative process of real estate geography. Real estate change involves a series of feedback loops between perceptions, social conditions, and risk.

Source: CCIM 102 *Real Estate Market Analysis*. Chicago: CCIM Press.

therefore inseparably linked to financial markets geographically remote from the development.

Conclusion

The real estate geographer creates due diligence documentation, and based on that documentation, he or she either recommends decisions or makes judgment regarding questions such as the following:

Where are new projects likely to emerge, and what effect could they have on investment decisions?

Which submarkets are most defensive from the perspective of supply and demand balance?

Where are the best opportunities, considering risk, for the most profitable investment?

Where are the opportunities within mature, emerging, or active markets for specific product types? Where are the attractive market niches?

What specific locations and which real estate asset types are likely to experience the greatest level of appreciation and/or be the most resilient if the market turns?

The real estate decision must satisfy conditions of the “geospatial feasibilities”: geospatial market feasibility and geospatial location/site feasibility. The real estate decision must also satisfy conditions of financial feasibility. Evaluation of financial feasibility depends on both the input of the real estate geographer and the input of financial data arising from markets geographically remote from the project site. Omnipresent in the background is the consideration for risk from the tumults of geopolitical and geosocial interaction with the real estate asset. In these ways, the real estate geographer brings to the business decision the “location, location, location” component of real estate, and “information arbitrage.”

REALISM

Realism is a philosophy that understands the world as relational, causality as contingent, and knowledge as socially produced. It gained prominence in geography during the 1980s as an analytical framework for thinking about and “practicing” both social science (critical realism) and natural science (transcendental realism). This distinction between the social and natural sciences

is inherent to a realist separation between natural and social “kinds”: Society is recognized as an open system that can never replicate the closed conditions of a laboratory, and institutions and actors are understood to be in a constant state of flux as compared with the more intransitive physical phenomena of the natural world. This is consonant with a realist ontology, which posits the existence of a reality outside human consciousness that is independent of the social construction of nature. As an epistemology, realism asserts that we can actually know something about this world beyond our cognition of it.

To “know” something about the world in the realist sense is to explain phenomena—both physical and social—in terms of their causality. Realism, however, rejects the conflation of explanation with prediction under logical positivism, which explains phenomena in terms of the repeatability and replicability of experimental results. In contrast, realism maintains that explanation warrants an understanding of the structures that allow things—events and phenomena—to happen. Structures are the elements internal to a phenomenon that demonstrate, or have inherent susceptibilities toward, particular kinds of “behavior” or action. Causal powers are enacted and expressed through the mechanisms of a structure. The realization or activation of this autonomous force, however, depends on the circumstances or the context in which things occur.

Realism explains how things happen by analytically separating out these mechanisms of causality. There are two kinds of relations between phenomena and their generative causes: (1) necessary and (2) contingent. Necessary conditions are the internal properties of a relation, wherein the event or phenomena observed cannot “be” or occur as essentially that which “it is” in the absence of a particular relation. For instance, a “slave” can only be a slave in relation to a “master.” For a mechanism to be causal, it must be a necessary condition for a phenomenon. Contingent conditions are the external properties of a relation or coincidences of coexistence. They describe the possibility for things to happen in terms of both the properties of phenomena and the circumstances of context. Andrew Sayer provides the example of gunpowder: Gunpowder has certain properties, such as the ability to

explode; explosion, however, depends on a spark to cause that explosion.

Mechanisms and structures are not always empirically discernible and must therefore be elucidated via rational abstraction. This holds in particular for causality in the social world, where the mechanisms that operate are both myriad and often unobservable. Abstraction involves the theoretical identification and conceptual isolation of the essential features or salient attributes of an event or phenomenon on the basis of its relations with, as opposed to similarities to, other entities. Abstraction is the basis for concrete research, which involves the “testing” of abstraction in the real world via empirical study to assess the “fit” or explanatory power of those abstractions. Empirical evidence may then lead to an adjustment of the abstraction such that the conceptualization yields a consistent picture of the world. This is an iterative process as it is through repeated abstraction—and grounding in empirics—that the difference between necessary and contingent conditions for causation can be elicited.

In the natural sciences, abstraction seeks to eke out the causal mechanisms generative of the observed events of scientific experiments. This emphasis on the causal contingency of scientific phenomena constitutes a rethinking of positivistic approaches to science, which involve the generalization of relations among empirical events, thereby failing to provide an account of causation by considering outcomes of experimentation as sufficient for cause.

In the social sciences, realism seeks to explain causality in terms of the internal relations between agency and structure, as in structuration theory. Realism maintains that there is no constant relating causes to events in the social world because social phenomena are unbounded and the effects produced by any one combination of relations will produce radically different results at any one time. The ways in which structures and their inherent properties intersect with other structures and human actors, however, create complex networks of interconnectivity that influence how people and other institutions act in society. The ability of a person to act—their agency—is often tied to their relations to other actors and structures such as social institutions. These structures are themselves simultaneously the outcomes of interrelations between other structures and agency.

Realism thus addresses how we come to know how structure and agency operate. Whereas structuration represented a deepening of Marxism by acknowledging both structure and agency, realism provided an analytical framework for integrating structure and agency in human geographic analysis. In so doing, realism relegated the role of “science” in geographic inquiry by allowing for the possibility of an emancipatory social science in acknowledging a material ground in which to enact meaningful social change.

In acknowledging that empirical observation is the fundamental way in which structures are discovered, realism moved geography away from the notion that theory alone can serve as the basis for explanation by clarifying the need for both theory and empirics in its insistence on theoretically informed concrete research. Most important, realism elevated the position of geography in the social sciences by arguing that structures of social relations are indelibly bound up with their spatial configuration. Space is central to this configuration because it is a contingent circumstance: “Things” may or may not be realized depending on *where* (and when) they occur. Structures moreover do not exist independently of, or somehow prior to, space: They are ontologically inseparable. In geography, this manifests itself particularly as a concern with economic and urban processes, giving rise to localities research in the 1980s. Its emphasis on analysis, however, opened realism to critiquing on the basis that it was blind to the politics of representation by postmodernist and poststructuralist frameworks, which privileged description over abstraction.

RECLUS, ÉLISÉE (1830–1905)

Élisée Reclus was an influential 19th-century geographer, even though he did not hold an official university position until late in his career. He was widely recognized for his scholarly writings on anarchism and geography, which informed his political activism.

His revolutionary mien reflects diverse influences. He was born into a large family in the Gironde Département of southwestern France. His father served as a Protestant pastor in a rural culture dominated by Catholicism. He eventually abandoned organized religion, but he retained a missionary zeal for political dissent and social equality, inculcated in him by his family. His formal university training included stints at several Protestant religious schools in France and Germany. He also attended lectures at the University of Berlin given by the celebrated German geographer, Karl Ritter. Events in the wider world also affected his intellectual development. He was a political activist, vocally protesting the 1851 coup d'état by Louis-Napoleon. Fearing reprisal, he fled France, eventually traveling to the United States, where he settled in Louisiana. The idealized notion he had of Southern plantation culture was quickly dispelled. He was horrified by American slavery, which he viewed as just one more instance of the injustice of capitalism.

By the 1860s, Reclus had returned to France and embarked on a prolific publishing career. His most notable works include the 19-volume *Géographie Universelle* (1876–1894) and the 6-volume *L'Homme et la Terre* (1905–1908), published posthumously. He combined his interest in geography and egalitarianism with ideas from Karl Marx, Pierre Joseph Proudhon, and Michael

Bakunin. Reclus, like his contemporary Peter Kropotkin, was concerned about the social inequality wrought by capitalism and statism. In response, Reclus advocated a society based on decentralized communities that embraced principles of cooperation, self-determination, and egalitarianism—including gender and racial equality. More than Kropotkin or other anarchist geographers, Reclus urged communities to coexist with nature rather than to dominate it. He was not afraid to put his intellectual beliefs into practice. For example, he participated in the 1871 Paris Commune, which ultimately led to his expulsion from France.

Reclus had a lasting impact on geography and planning. His regional approach influenced later geographers such as Vidal de la Blache. Reclus also inspired Ebenezer Howard's Garden City movement and Patrick Geddes's decentralized regional planning. More recently, French geographers used the acronym RECLUS (*Réseau d'Etudes des Changements dans les Localizations et les Unités Spatiales* [Network Studies of Changes in the Localizations and Spatial Units]) to describe research initiatives focused on localities. One hundred years after his death, Reclus remains a vital figure in the field of geography.

RECYCLING OF MUNICIPAL SOLID WASTE

The term *recycling* has become commonplace in the lexicon of environmentalists since the so-called environmental crisis of the 1960s and early 1970s. Indeed, recycling is commonly associated

with a process whereby materials are remade into the same or different products. This process needs to be distinguished from a plethora of other terms such as *waste reduction* or *minimization* (the process of actively seeking to reduce waste by not purchasing or using materials in the first place), *reuse* (the use of a product or material for the same or other purpose without a change to the material itself), and the rise in charitable giving, which is a formalized system of reusing materials. This entry explores recycling by examining both its cultural-historical context and the current theoretical and policy-driven research being undertaken by geographers.

In discussing recycling, caution should be exercised in the ways in which researchers approach the notion of *waste*, which is largely a term that has developed in industrial and postindustrial societies, where the economics of resource use are such that materials can be “wasted.” Accordingly, these everyday terms need to be placed within a cultural and historical context. First, recycling is still undoubtedly a term applied more widely in Western industrialized societies, although the emerging economies of China and India are now beginning to grapple with the major issues of waste management at a range of scales. Second, recycling of waste has a far longer history than many people appreciate and one that was not conventionally linked to environmental concerns. These “traditional” forms of recycling have been focused on economic imperatives that have necessitated the innovative reuse or recycling of products, particularly in times of economic strain, such as the National Salvage Campaigns developed during and after World War II in Britain. Third, it should be noted that the contemporary social constructions of wastes are closely aligned to the conspicuous levels of consumption that emerged after World War II in Western countries and to the debates surrounding how people and governments address waste, which needs to be seen in the wider context of what we can term *sustainable consumption*.

This entry also explicitly considers contemporary notions of waste recycling and is focused on what is termed *municipal solid waste* (MSW). This refers to household and other commercial (nonindustrial) waste, commonly collected from individual households and retail and catering businesses.

The Wheelabrator waste-to-energy plant in Worcester, Massachusetts, converts 2,000 tons of garbage to electricity every day.

Source: Bill Eager, National Renewable Energy Laboratory.

Although both academic and policy-related attention has focused on MSW, it should be noted that for most countries, this is a relatively minor proportion of the total waste stream. For example, in England and Wales, the total amount of waste collected during 2004 was 335 million tons. Of this, only 9% was household waste.

In terms of the political imperatives for recycling of MSW, a range of initiatives has developed to encourage governments and individuals to recycle their waste. Perhaps the boldest international statement was that provided in Chapter 21 of the United Nations Agenda 21 document, where waste was highlighted as a key issue. From this international scale, both economic regions (e.g., the European Union) and national states have developed comprehensive policies for tackling the waste problem, finally percolating down to local authorities. This effort has been given greater impetus recently with concerns over the role played by methane gases emitted from waste landfill sites in

contributing to global climate change. For this reason, and also given the lack of suitable space for land-filling wastes and opposition to waste incineration, the key environmental issue for many local authorities and communities is how to respond to the growing amounts of MSW.

Research exploring recycling of MSW has generally been focused on the problems associated with low levels of recycling, particularly among households and individuals. This research has a long tradition and has been dominated by behavioral studies, mostly undertaken in North America by social and environmental psychologists. Researchers in this field have identified a range of sociostructural and psychologically based variables that influence participation in recycling schemes, which usually depends on the type of recycling activity concerned (e.g., curbside collection or “bring” sites) and the material involved. Indeed, in line with research on other environmental behaviors (e.g., energy or water conservation),

Cardboard recycling at Waste Management in Englewood, Colorado

Source: Warren Gretz, National Renewable Energy Laboratory.

evidence has emerged that different groups in society, with discrete lifestyle aspirations and behaviors, will react in different ways to recycling initiatives, with the potential for policymakers to target specific initiatives at specific groups through a form of social marketing.

However, emerging research agendas have also developed in recent years, which have either focused attention away from households or have explored alternative theoretical approaches to studying waste in the home environment. First, a growing body of research explores the relationships between MSW and government decision making, through exploring the governance structures and processes at the community, regional, and national scales. Second,

there has been increasing interest in the ways in which policies and practices of waste management differ within different contexts, notably in the workplace and in leisure and tourism spaces. This research has sought to develop existing theories of waste management and behavioral commitments to explore the potential differences between these contexts. Third, an emerging discourse in the social science of waste (or “rubbish”) is developing around a critique of the so-called throwaway society, in which the assumptions made by many social scientists that “waste” is related to a simple process of consumption are problematized. This emerging approach asserts that understanding the ways in which objects (or “things”) relate to social

relations and interactions is critical in appreciating the ways in which objects become used and wasted in the home.

Recycling therefore represents a politically and intellectually dynamic theme in geographical research and is a theme that will continue to develop as debates concerning resource management, climate change, and human responses to these challenges develop.

REDISTRICTING

A traditional focus for political geographers, particularly those interested in U.S. politics, is redistricting—the process of changing the boundaries of electoral districts to maintain equal populations. It is a critical part of the maintenance of constituency-based systems, particularly those with single-member districts. In international contexts, redistricting is often called boundary delimitation, and in Commonwealth countries, it is called redistribution. In

the United States, the term is sometimes used interchangeably with reapportionment, although the latter word more precisely refers to the redistribution of congressional seats among states following the decennial census. Manipulation of redistricting for electoral advantage is called *gerrymandering*.

Interest in redistricting stems from the fact that the way district boundaries are drawn can have a far-reaching impact on the distribution of political power. Placing large numbers of one group of voters in a single district (packing) or spreading them out over many districts (cracking) are just two of the strategies used by map drawers intent on tilting the balance in favor of one side or the other. Redistricting contributes to the levels of bias and responsiveness in single-member district systems. Bias, the degree to which the ratio of votes cast to seats won varies from 1:1, can undermine the basic fairness of an electoral system. The responsiveness of district-based systems, or their ability to translate temporal changes in voter preferences to changes in the distribution of seats, is constrained by the creation of safe districts and enhanced by competitive ones. The creation of safe districts—a usual result of gerrymandering—is often blamed in the United States for contributing to the polarization of the two main parties, as the party primarily becomes the key contestant and appeal to independents and crossover voters is devalued.

Redistricting in the United States

After the constitutional requirement for population equality, redistricting in the United States is driven by the intersecting interests of partisanship and race. It is also heavily litigated. Although a few states involve nonpartisan commissions in their redistricting process, most allow the party in control of the legislature and the governor's mansion to use the redistricting process to boost their political fortunes. The U.S. Supreme Court, while not completely closing the door on the possibility that a partisan gerrymander might violate the Constitution, has thus far refused to intervene. Judges have been much more active, however, in redistricting cases in which racial or ethnic minority groups are alleged to have been disadvantaged. The Voting Rights Act, originally passed in 1965 and renewed repeatedly by Congress since, allows the federal government and private plaintiffs to

This is the original cartoon of “The Gerry-Mander,” the political cartoon that led to the coining of the term *gerrymander*. The district depicted in the cartoon was created by the Massachusetts legislature to favor the incumbent Democratic-Republican party candidates of Governor Elbridge Gerry over the Federalists in 1812.

challenge state and local redistricting plans that they allege dilute the ability of minority voters to elect candidates of their choice. The result has been racial gerrymandering by those states with significant numbers of minority voters. Since the 1990s, racial gerrymandering has faced an increasingly skeptical Court, starting with the 1993 decision in *Shaw v. Reno*, in which a 5–4 majority struck down the formation of a serpentine North Carolina 12th congressional district, which for much of its length was no wider than the interstate highway it followed. The Court’s tolerance of the continued use of racial and ethnic data to draw redistricting plans remains very much in doubt.

Redistricting in the United Kingdom, Canada, and Australia

Reformers in the United States often look to the models used by the United Kingdom, Canada, and Australia, where line drawing has been turned over to commissions in an effort to reduce or eliminate partisan maneuvering. In Britain, four Boundary Commissions review and amend parliamentary constituency boundaries periodically, while in Canada, Electoral Boundaries Commissions in each province are responsible for changing district lines. In Australia, redistricting is performed by the Australian Election Commission and its state and territorial equivalents, and political interference is a crime.

Despite these steps, scholars have found significant bias even in such regulated nonpartisan processes. Geographers in Britain, for example, found that pro-Labour bias in the 2005 general election resulted from that party's strength in the smaller constituencies, helping it win 56.5% of the parliamentary seats with only 36.2% of the votes cast.

Scholarly Geographic Interest in Redistricting

A number of facets of redistricting and district design have particularly drawn the interest of geographers. The criteria, both formal and informal, used by map drawers and legislators in formulating their plans has been a constant focus, since criteria such as the compactness of districts (a focus in *Shaw*), district contiguity, and respect for communities of interest and existing political boundaries have obvious spatial qualities. Generally, geographers have been skeptical of oddly shaped districts, interpreting their presence as a sign of gerrymandering. This skepticism has been most pronounced among political cartographers; others have argued that this view privileges district aesthetics over racial or political fairness. In any case, an adequate quantitative measure of noncompactness has proven elusive.

Increasingly, redistricting has relied on geographic information systems (GIS) to handle the massive spatial, political, and demographic data used to draw new district plans. Particularly since the 1990s, the widespread use of GIS has led to the rapid creation of alternative district plans and fine-grained analysis of the impact of specific plans on political parties and racial and ethnic groups. Some have seen a pernicious impact, however, arguing that the improved technology has encouraged map drawers to ignore the existing political boundaries and to refine the gerrymanders and led to the creation of the sort of oddly shaped districts that triggered Supreme Court censure and public disdain. Despite these fears, future rounds of redistricting will continue to rely heavily on GIS.

REFUGEES

The concept of a refugee is an inherently geographical one, a barometer of political instability and the embodiment of forced migration. In current usage, the term has two main meanings; one is colloquial and often political, while the other is legal. In the wake of the humanitarian disaster that emerged after Hurricane Katrina hit the southern coast of the United States in August 2005, the media called those Americans huddled on the rooftops of their homes awaiting help and people who had sought shelter in the local sports stadium “refugees.” Many refused the term, saying that they did not want to be racialized as poor, African, or other. Yet others defended the term as appropriate, saying that the Bush administration was neither able nor willing to assist and protect its own citizens in this time of need. In both cases, the term was politicized for specific reasons, yet in legal terms, the survivors of Hurricane Katrina were not legal refugees but rather internally displaced persons. Likewise, references are made to “environmental refugees” affected by global warming or natural disasters.

The legal meaning of *refugee* is more straightforward; it is rooted in the Westphalian state system in which citizens, or nationals, belong to sovereign states that provide protection to them. Refugees are seen, then, as a kind of aberration to these norms of statehood. The Protestant

Huguenots who fled France under the rule of Louis XIV in 1685 are thought to be the first modern refugees. The French king revoked protection for the Huguenots to worship their religion without persecution from the state, which led to their displacement.

According to international law, specifically the 1951 Convention Relating to the Status of Refugees, a refugee is any person who

as a result of events occurring before 1 January 1951 and owing to well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group or political opinion, is outside the country of his [*sic*] nationality and is unable or, owing to such fear, is unwilling to avail himself of the protection of that country; or who, not having a nationality and being outside the country of his former habitual residence as a result of such events, is unable or, owing to such fear, is unwilling to return to it.

One of the major tenets of refugee law, then, is the principle of *nonrefoulement*—that is, a refugee will not be returned to her or his country by force (*refoulement*).

Refugees fall under the rubric of international human rights law as well as refugee law, though as Hannah Arendt noted after World War II, the actual protection afforded by such rights was and remains questionable. In 1966, two legally binding human rights instruments were created to protect civil and political rights, on the one hand, and economic, social, and cultural rights, on the other. The International Covenant on Civil and Political Rights most closely expresses the emphasis of the Convention. It ensures respect for democratic principles and nondiscrimination. The Covenant on Economic, Social, and Cultural Rights includes provisions that are more applicable to developing countries than to the highly industrialized ones, such as the right to food, shelter, and basic medical and educational services.

Despite the fact that 144 states were party to the 1951 Convention or its 1967 Protocol in 2007, the definition of refugee remains both explicitly and implicitly Eurocentric. The Refugee Convention demarcated geographical and historical limits: It applied to refugees in Europe displaced by events that occurred prior to 1951. The

Convention's definition of refugee is spatially coded as European. Substantively, its emphasis on persecution based on civil and political status as grounds for refugee status expresses the particular ideological debates of post-World War II European politics, particularly the perceived threats of communism and another Holocaust. The 1967 Protocol, relating to the status of refugees, amended the 1951 Convention. While it rescinded the spatial and temporal restrictions of the Convention by lifting the European-centered, pre-1951 stipulations, it merely created equal access for all member nations to a legal instrument that remained substantively Eurocentric in focus.

Two correctives to the Eurocentrism of the 1951 Convention and 1967 Protocol are worth noting. First, the 1969 Organization of African Unity (OAU) Convention Governing the Specific Aspects of Refugee Problems in Africa not only broadened but also reformulated the definition of refugee. It included the 1951 Convention definition but added the provision that

the term refugee shall also apply to every person who, owing to external aggression, occupation, foreign domination or events seriously disturbing public order in either part or the whole of his [*sic*] country or origin or nationality, is compelled to leave his place of habitual residence in order to seek refuge in another place outside his country of origin or nationality. (Article 1.2)

As a legal convention, this provision recognized that histories of colonialism were themselves the basis of conflict and displacement, regardless of the persecution element. Second, in 1984, the Cartagena Declaration on Refugees was adopted by 10 Latin American states. Like the OAU Convention, it represents a regional approach to recognize and improve on the inadequacy of the Convention definition. The definition derived from the Cartagena Declaration goes further than that of the Convention to include claims based on internal conflicts and massive violations of human rights and the idea of group designation. However, as a declaration and not law, it is not binding.

Geographers today have argued that legal definitions and protections afforded to refugees through the international protection regime are increasingly irrelevant as many of the signatories

In this October 22, 2009, photo, two residents of the State House settlement in Hargeisa in Northwest Somalia walk amid makeshift shelters housing refugees displaced by civil war. The conflict in South and Central Somalia is forcing Somalis to flee northward with their children to safety—a perilous weeklong journey by truck that exposes them to armed gangs that assault them sexually and deprive them of their last few possessions. The northern regions of Puntland and Somaliland, with their relative political stability, attract tens of thousands of the displaced, depleting still further the scant resources of sometimes unwelcoming local communities.

to the Convention and Protocol in the global North seek to prevent all uninvited migrants, including asylum seekers, from entering their territory. Some have called the use of geographical tactics of exclusion to preclude seeking asylum as *neorefoulement*. If would-be refugees cannot make asylum claims, international laws governing their eligibility become irrelevant.

Such geopolitics of externalization efforts by countries in the global North to manage refugees in the global South where possible may well contribute to a growing issue: protracted refugee situations. The United Nations High Commissioner for Refugees (UNHCR, 2006) defines a protracted refugee situation as one in which refugees find themselves in a long-lasting and intractable state

of limbo: “Their lives may not be at risk, but their basic rights and essential economic, social and psychological needs remain unfulfilled after years in exile” (p. 106). Sometimes refugees live in camps for years on end; *refugee warehousing* is another term used to describe the plight of those waiting in confined quarters (U.S. Committee for Refugees and Immigrants [USCRI], 2007). The USCRI reported that there were 8.8 million people in protracted refugee situations at the end of 2006. The average waiting time for refugees to obtain a durable solution has increased from 9 yrs. (years) in 1993 to 17 yrs. in 2003.

Geographers and anthropologists have also analyzed the politics of representation among refugees. Humanitarian actors who respond to

their plight often render them as objects of camp management or as populations where disorder is ordered. Malkki (1996) argues that “history tends to get leached out of figure of the refugee, as imagined by their administrators” (p. 385). Malkki adds that these standardizing discursive and representational forms that have the tendency to silence people categorized as “refugees” have made their way into the media that report on forced migration.

REGIONAL ECONOMIC DEVELOPMENT

Regional economic development (RED) refers to changes in the economic structure of a region that increase the range and value of economic activity conducted within it. The geographic scale generally refers to areas circumscribed by the regular home and work locations of most people. This is

usually a territory smaller than the nation-state; in poorer, rural cultures it may be the village, while in wealthy urban cultures it may be an extended metropolitan area.

To take an 18th-century liberal view of political economy, the purpose of an economy and of economic development is to improve people's material well-being where they live. Since the employment, education, and health of people depend on the opportunities available in their regions, RED and its sustainability across generations are important processes. Individuals, families, and governments have huge psychological, social, and economic investments in local regions: a sense of history and shared future, personal wealth in the form of real estate, and investment in the form of physical infrastructure. These are powerful forces that motivate governments at all levels toward a concern for regional economies.

What allows for sustainable employment of the people, land, and resources of a region? Given the context of a subnational region, capital, people, products, and ideas can move among regions, so that the question may be rephrased as follows: What situations can lead to the continued development of a region's capital, labor, and resources to increase its level of economic activity? This entry explores three requisites: (1) capital to provide the power to organize resources, infrastructure, and labor before they realize a return; (2) competencies to organize these factors in ways that sustain demand and returns to capital; and (3) infrastructure and institutional arrangements that support capital investment and individuals' and organizations' competencies.

Attracting and Retaining Capital

Capitalism is motivated by the demand for ever higher returns to the owners of capital, and those returns are generally sought through increasing the technical and social division of labor—across larger scales—by establishing divisions among social groups (e.g., women, minorities, immigrants), so that ever newer groups can be exploited as they are given elements of production, to move some operations to places where labor is cheaper, or by taking over (or making

more use of) other firms or other sectors. Capitalist accumulation requires some displacement of costs outside what we might call the formal accounting system: to geographic spaces outside the system (e.g., other countries), to members of the family (generally women and children) as unpaid labor, to parts of the natural world that have not been valorized (e.g., the creation of value from little-known species or from human genes), to particular social groups, or to future generations.

Under the neoliberalism that has taken hold over much of the world, regions attract capital based on the following:

1. New frontiers for exploitation are present—unlimited land, labor, or resources and the government subsidy of capital investment and corporate operations. For example, the rapid growth of investment in many Chinese cities, which have become the center for the world's consumer goods manufacturing, is motivated in part by the influx of workers from inland, rural areas, and the returns are earned in part from externalizing the costs onto the physical environment at a dizzying rate.
2. The premium paid for local availability of scarce resources, such as extracted natural resources, an excellent harbor, or highly specialized labor, reduces the mobility of capital to be invested to gain a return from those resources.
3. More subtly, capital investment is attracted toward the regular creation of new ideas and ways of operating that are unique to the local region. This local knowledge creates new (and therefore monopolized) products or that which uniquely increases the returns to operating in that region.

One can name other sources of capital attraction. Some, such as the investment in booming retirement communities in warm, coastal areas of the United States, can be traced to (1) above: available land, attractive climate, and government subsidy in the form of low taxes and limited public support for infrastructure such as schools. Rapidly growing regions can then benefit from a deepening division of labor, through which

specialized services are established to increase the profitability of capital investment in enterprises that can avail themselves of these services. Finally, in some contexts, capital is invested by government fiat. In the United States, military bases exemplify this limited government deployment of capital resources.

Knowledge and Competencies as Sources of Advantage

Much recent writing has argued that useful knowledge is a linchpin of capital productivity and that despite the seeming mobility of “knowledge,” some of its development and use is tied to particular places. “Organizational competence” is the ability of an organization to make use of information to improve its operations. This concept suggests a distinction among information (“data”), knowledge (understanding processes), and competence. Individuals make use of prior education, training, and experience to turn tasks, information, and experience into knowledge—whether their tasks entail product development, process improvement, shop floor production or service, marketing, or supply chain management. Individuals receive information all day long and have to create useful knowledge from their experiments and experiences. However, organizations or even regions can have competencies distinct from (and less mobile than) the knowledge of the individuals within those organizations.

Organizations gain competencies beyond the knowledge of individuals through the division of labor—the specialization of tasks and knowledge so that no individual possesses the ability of the whole. In addition to the division of information and knowledge, the more general process of creating organizational practices and procedures reduces the dependence of the organization on individuals, except insofar as individuals develop tacit ways of working with—or around—each other. Defined this way, organizational competence is *sine qua non* for a successful organization, which must manage its resources in response to varying characteristics and changes in its suppliers, buyers, regulations, and so on. However, as technological, marketing,

and financial sophistication become widespread, capitalists who want to see more than a bare-minimum return need to find new competencies: new products, cheaper production methods and locations, and new ways of managing supply chains and product distribution.

Organizations can increase this type of competence through concerted efforts to integrate knowledge among their members; to communicate codified and tacit knowledge among organizations; to work with public sector sources of education, training, and knowledge production; and to develop intermediaries that broker knowledge and skills among organizations. Through the agglomeration of people and institutions, some of these competence-building activities result in localized and sustainable advantages of particular regions for particular activities.

Institutions and Infrastructure

Individuals, societies, and organizations can undertake a range of actions to develop and use new knowledge and competencies:

Governments spend funds on education, research, and development and design incentives for individuals and organizations to engage in knowledge generation. Governments also lay the regulatory framework for firms' ability to lay claim to intellectual property, including, in some settings, knowledge originating in the public or common realm.

Firms (and other formal organizations) can gain knowledge and expertise from outside: through market purchases of equipment or specialized services, through observation and imitation, through hiring new people, or through formal collaborations.

Firms can work internally on technical development; systems improvement in finance, marketing, and procurement; and generating systems for continuous process monitoring and improvement. Despite the cost of such internal development, this ability to develop and deploy new systems, and to assess their value, is key to sustainable knowledge and competences.

Individuals within the organization gain capability

and confidence, and the resultant knowledge is unique to the organization.

Yet capital, competencies, and individuals remain more geographically mobile than a region itself. What sources of regional advantage tend to attract and bind capital investment? Table 1 offers a simple answer to this question. Private capital (or in a mixed economy, mobile capital whatever the source) is what's required for any large-scale development and employment of local resources. The last five rows describe geographically fixed assets of regions, important to sustain the economic development of knowledge-based activity.

RED policy has increasingly recognized that residents and institutions are the "stickiest" regional assets. Rather than chasing and subsidizing private capital investment, state, provincial, and local governments should attempt to draw residents into the labor force (through education, child care, transit), subsidize their occupational attainment and further training, provide high-quality physical infrastructure, and catalyze mixed-sector forums for information sharing about their human resource needs.

Conclusion

From a trade theory perspective, each region needs to develop comparative advantage in economic activities based on

- its unique configuration of resources—efficiency insists that these resources be used to their mutual advantage—and
- institutional arrangements (organizations; interorganizational formal institutions, rules, and public policies; and informal norms such as communication and cooperation), which influence the ability of individual agents to maximize the use of the region's resources.

In other words, it is necessary to identify regional assets that are relatively fixed and public investment and policies that support and improve those assets. Whether the resources are primarily natural and the activities are extractive or agricultural, or the resources are primarily human and the activities are new products and services, infrastructure, institutions, and organizational

<i>Asset or Source of Advantage</i>	<i>Mobility</i>	<i>Sustainable Across Generations?</i>	<i>Importance to Knowledge-Based Activity</i>
Public subsidy (tax breaks) ^a	Extreme ^b	Perhaps	Somewhat
Externalization of environmental costs	Extreme	No	Not very
Private capital	Extreme	Yes, so long as the investors receive high returns	Very
Inexpensive labor ^c	Moderate	So long as interregional wage differentials exist	Somewhat
Specialized labor	Moderate	Yes, so long as the public, the corporate, and/or the household sectors invest	Very
Sources of new knowledge	Moderate	Yes, so long as the public and/or the corporate sectors invest	Very
Specialized suppliers and services	Moderate	Yes	Very
Networks for communication and synergy of new knowledge	Moderate	Yes	Very
Public infrastructure	None	Yes, so long as the public sector continues to invest	Very

Table 1 Mobility, sustainability, and importance of regional assets for knowledge-based activity

Source: Author.

a. Implies externalization of costs onto households or more heavily taxed businesses.

b. Mobile in the sense that other regions can offer the same or better advantages by decision or fiat.

c. The result of migration from low-wage or rural settings, government discouragement of labor unions, lack of a binding minimum wage; implies externalization of costs onto the public sector, the household, or low-wage workers themselves.

competencies are required to attract and hold capital and mobile residents.

REGIONAL ENVIRONMENTAL PLANNING

Regional environmental planning can be either a statutory process or a less formal one, undertaken, in either case, by subnational scales of government to promote sustainable development within their jurisdiction. Planning regulations and procedures were formalized in developed countries during the 20th century as a means of controlling land use. Proposed changes to land use (e.g., building a road or constructing domestic or industrial premises) were made subject to a review process under the auspices of the local government and with opportunity for public participation. This was effectively a form of environmental governance, before either popular or institutional concern for the environment became commonplace. These procedures are still fundamental to land use regulation but have been enveloped in a complex multiscale framework designed to contribute more actively to the promotion of sustainable development. This entry focuses on the formal process of regional environmental planning, as seen in the European Union concept of spatial planning, using the practice of the United Kingdom as an example.

It briefly reviews other practices and relevant scholarly work.

Increasing interest in environmental issues since the 1970s has coincided with an era of enhanced governmental involvement in the promotion of economic development at the regional and local scales. Reconciling these interests, alongside social considerations (both the provision of essential services and spatial equity in the distribution of economic activities are seen as undesirable neighbors), is fundamental to the promotion of sustainable development. The concept of spatial planning, as institutionalized in the European Union (EU), was designed to accomplish this. Spatial planning is in part a matter of provision of services needed for existing and projected development (e.g., schools, transport, hospitals, energy generation, waste, minerals), recommending where within the jurisdiction of the plan relevant facilities should be located and also minimizing the impact of necessary development on the environment at both the site of development and beyond. Importantly, the various services should be considered in an integrated fashion—that is, the planning should involve cooperation both between different local authorities and also between different areas of responsibility, both within and between local authorities.

The “region” can vary in scale according to context from the subnational to multinational and might or might not be politically defined. The EU vision of spatial planning considers both supranational regions within the EU and subnational regions within the member states. In the United Kingdom, a subnational regional scale for planning was established with the creation of the Regional Assemblies. The presently recognized regions (devolved administrations and groups of preexisting local government units [i.e., county councils and unitary authorities] within England) were defined for the purposes of both economic development and regional planning by the creation of the Regional Development Agencies Act of 1998. Although presently subject to reorganization, the regional scale continues to be the level of governance at which spatial planning is based through the medium of the Regional Single Strategy. The latter involves the cooperation of multiple local authorities as well as nongovernmental organizations (Table 1) and forms the context within which more detailed planning occurs at

<i>Scale</i>	<i>Constituent Bodies</i>	<i>Relevant Function</i>	<i>Example: Planning</i>	<i>Example: Waste</i>
Supranational	European Union	Environmental protection and harmonization	Strategic Environmental Assessment Directive	Waste Framework Directive and Landfill Directive
National	National government	National regulations		
	Department of Communities and Local Government	Oversees planning policy	Planning policy statements and guidance	
	Infrastructure Planning Commission		Oversees applications for nationally significant infrastructure projects	
	Department for Environment Food and Rural Affairs	Oversees sustainable development, including environmental protection		Waste Strategy for England 2007
	Environment Agency	Consulted on plans/projects with potentially significant environmental impact		Regulates waste operators via environmental permitting regime
Regional	Local Authority Leaders' Boards; Government Office, Regional Development Agency; input from Local Authorities; Local Strategic Partnerships, regulatory bodies; industry, conservation bodies	Regional Single Strategy	Combined economic and environmental plan integrating multiple sectors (e.g., energy, transport, housing) and subject to strategic environmental assessment	
Local	Unitary authorities, county councils district/metropolitan councils	Local Development Framework: Plans (e.g., waste) subject to strategic environmental assessment	Review and decide on planning applications relating to specific projects	Waste collection and/or disposal
				Statutory targets to meet for recycling household waste;
Site specific	Public and/or private bodies	Proposing development covered by the above regulations/plans	Subject to environmental impact assessment and permitting	Individual waste facilities (e.g., energy from waste or recycling centers)

Table 1 Policy context of regional environmental planning in England

Source: Adapted from Deutz, P., Neighbour, G. B., & McGuire, M. A. (2010). Integrating sustainable resource management into product design: Sustainability as a functional requirement. In *Sustainable Development*, 18(6). DOI: 10.1002/sd.469.

the local authority level and for specific services. Regional and local authorities are required to undertake appraisals of the environmental impact of their plans under a Strategic Environmental Assessment (SEA) Directive. Proposals for specific developments (e.g., a wind energy farm or wastewater treatment facility) are then subjected to the more internationally widespread practice of environmental impact assessment.

Outside the EU, the process of regional environmental planning is less formalized and less integrated into the broader considerations of sustainable development. In the United States, for example, there is no national drive to promote an integrated approach to regional planning comparable with that in the EU. There are, however, ideas such as Smart Growth that promote consideration of the environment in North American regional and urban development. Regional environmental planning takes place with respect to specific issues, for example, air or water pollution control, or conservation, particularly in metropolitan regions.

There are several difficulties with environmental planning on a regional scale. Regions are not politically independent territories. Policy is mandated from both national and supranational levels, and delivery can be the responsibility of smaller-scale units of governance (Table 1). Furthermore, in areas of service provision where privatization has taken the responsibility for day-to-day operations out of the control of local authorities, the local or regional government has limited potential to bring about the developments it may consider advantageous. Additionally, public concerns about development that have long found a voice through the planning process are also raised by the prospects of developments (e.g., wind farms) that may be considered environmentally beneficial on a national scale.

Scholarly work on regional environmental planning takes many forms. One line of research investigates the governance structures associated with planning and the associated assessments. This includes work that links regional environmental planning with the concept of the “new regionalism” approach to economic development. Other work is directed toward providing insights and/or knowledge that would be, or could be, usefully applied to regional environmental planning. Such

work includes studies of sustainability indicators—quantitative measures by which planners and others can assess progress toward sustainability. Related to this is work investigating the application of geographic information system (GIS)–based modeling to regional environmental planning and management. Work is also in progress to tackle regional environmental planning from the point of view of limiting the impact of natural hazards.

REGIONAL GEOGRAPHY

In the popular conception of geography, the discipline is concerned with the study of regions and little else. Geographers have examined regions at a variety of spatial scales and from a diversity of conceptual perspectives. Regions have long been

a central means by which geographers organized data and made sense of the world's natural and social landscapes. Few topics have been more central to geography's history and disciplinary identity. Regions continue to form a mainstay of elementary geography pedagogy, and many geographers specialize in the analysis of particular regions, ranging from tiny places to entire cultural realms. Regions mean different things at different times and can be defined in different ways depending on the particular issue involved. Regions are important in structuring popular geographical imaginations as well as public and private economic strategies. While this topic may appear to be relatively free from controversy, in fact the use of regions and their philosophical significance has been the source of considerable debate. Indeed, regional geography, which has declined in significance since its heyday in the mid 20th century, continues to play an important part of the discipline, albeit one that jostles uneasily alongside other, less regionally oriented perspectives.

Classical Regional Geography

Since the Classical Age of Greece, regions have played a central role in geography as a means to collect, organize, and give meaning to spatial distributions. Many classical scholars, such as Ptolemy, wrote encyclopedic accounts that were largely regional descriptions of the known world. In the 17th century, Bernhard Varenius (1622–1650) wrote the *Geographia Generalis*, a volume that became a major textbook in Europe for the next 150 years and was translated into English by Newton. Varenius distinguished between *specific geography*, which was concerned with the unique character of places, and what he called *general geography*, which was concerned with universal laws.

In the 19th century, three figures loomed large in the formalization of regional geography. Carl Ritter (1779–1859) wrote the 19-volume *Erdkunde* (1818), a comprehensive world regional geography text, which emphasized the comparison and synthesis of facts through a regional approach, largely with religious goals in mind. Geography's purpose was to detect the holistic character of places. Comparative local studies

were to be the basis through which generalizations could be made. Ritter claimed to see evidence of divine plans in the world's geography, advocating a religious, teleological interpretation. Second, Paul Vidal de la Blache (1845–1918), widely seen as the founder of modern French geography, developed the notion of *genres de vie*, or local lifestyles, which celebrated the uniqueness of rural landscapes in the French *pays* (local, typically agrarian regions). Noting the variations across France in the face of a common climate, he maintained that culture, not nature, was primarily responsible, using this theme to bludgeon environmental determinism and introduce possibilism. Third, Alfred Hettner (1859–1941), in the Kantian tradition, defined geography in chorological terms, believing that the discipline's importance was maintained by its comprehensive, regional approach rather than its subject area and that synthesis was its greatest strength.

Areal Differentiation

The American version of regional geography reached its apex between the two World Wars with the ascent of this school of thought, variously labeled as areal differentiation, chorology, or regional description. The ascent of this view was to be found in the aftermath of environmental determinism, when the discipline's retreat from theory sharply differentiated it from other social sciences, which were then making great strides. Its embodiment is Richard Hartshorne (1899–1992) and his definitive landmark text *The Nature of Geography* (1939). Having studied under Hettner and thus heavily Kantian in outlook, Hartshorne made a variety of claims regarding regional geography as the definition of the discipline's core and claim to uniqueness within the academic division of labor. Geography was synthetic, like history, integrating the analysis of different phenomena as they were manifested in unique combinations in particular places. Regions allowed the analysis of both human and physical phenomena, transcending the growing schism between the two parts of the discipline. Because the complexity of the world is overwhelming, Hartshorne advocated the study of small regions with relatively little internal variation; accreting this into a mosaic that would

encompass larger areas. This view subscribed to a crude spatial determinism in which proximity came to stand for causality: Where things were was enough to ascertain their nature, and closer phenomena were more likely to be related than more distant ones. He well understood that regions are only tools and, in the vein of Kant, maintained that regions are only mental constructs—simplifications of the world the mind uses to impose order on the world.

Hartshorne considered regions to be essentially static and held little regard for the need to engage in the study of explanatory processes—that is, regional geography was to be only about appearances. This approach represented a spatialized version of the philosophy of empiricism—the assumption that facts and data are true or false without appeal to theory—with its roots in the British Enlightenment. In contrast, more recent approaches argue that all data are theory laden—that is, it is theory that informs us what facts are relevant to an issue at hand. There are no pure facts, as observations are always couched in terms of a theory: Observation requires interpretation, which requires theory in turn. Hartshornian chorology was the essence of inductive empiricism, and its Achilles heel was the inability to engage in abstraction.

American regional empiricism suffered a devastating set of setbacks in the 1950s as it was pushed aside by an increasingly assertive school of logical positivists. A famous paper by Fred Schaefer published in 1953 charged that Hartshorne's claim that geography alone studied the unique was naive, arrogant, and immature. All sciences face the problem of uniqueness, and explanation, as opposed to regional description, consisted of embedding the unique within a wider understanding of laws and causal processes. Schaefer opened the door to a heated debate about whether geography should be primarily concerned with the nomothetic—that is, the law seeking—or should be content with the idiographic (i.e., the unique). The rise of positivism saw the triumph of the nomothetic approach, and the discipline shifted from the study of all aspects of one place to one aspect of many places—a move that entailed a reorientation from the concrete to the abstract, from induction to deduction (i.e., an interest in theory and broad, abstract

principles), and from a concern with the specific to the pursuit of the universal. Ultimately, the demise of chorology saw the discipline change from a concern with regions without explanatory laws to one obsessed with laws devoid of regions. Some observers, such as Hart, maintained that regional geography nonetheless played an important role in minimizing armchair theorizing and in popularizing the discipline at large.

The New Regional Geography

In the 1980s, as postmodernism swept the field, geographers saw a renewed concern for regionalism, often called the localities school. Unlike the atheoretical, empiricist chorology of areal differentiation, this approach took theory seriously, embedding regions within wider understandings of capitalism, uneven development, and the spatial division of labor. Originally British in inspiration, it began with observations that ostensibly uniform processes such as deindustrialization occurred very differently in different places—that is, local contexts made a substantial difference to how that process unfolded. Doreen Massey used this line of thought to develop a geological metaphor of regional landscapes, in which their position within changing divisions of labor sedimented layer upon layer of investments on the landscape. Regions consist of a palimpsest unique to that place and reflecting their historical trajectory.

More broadly, the localities school implied that no social process unfolds in exactly the same way in different places. From the standpoint of the new localities school—*where* processes occur affects *how* they occur—causality and location are intertwined. This argument reflected the broader insertion of space into social theory in general and the mounting concern for a contextual social science. Such a line of thought dovetailed neatly with the growing popularity of views that emphasized the creative capacities of people and the contingency of social life. Localities were celebrated as spaces where the rich world of everyday life plays out. Thus, under chorology, the region was fetishized; under logical positivism, the region was dismissed; and under postmodernism, the region is celebrated as a source of difference in contrast to the smothering homogeneity of globalization.

The recognition of local uniqueness has become widespread throughout human geography today, and the region has, ironically, recaptured some of its time-honored status. Typically, such approaches tend to be multiscale in focus, invoking social processes at a variety of spatial scales. For example, regional geography today would do more than say that all places are embedded in a global economy: Rather than a simple process of telescoping from the global to the local, the global and the local should be seen as intertwined, or global in nature.

In sum, regions have played a central role in the history of geography as a discipline. Although geographers have long since jettisoned simplistic regional descriptions in favor of far more theoretically sophisticated views that seek to integrate broad processes with local contexts, regions continue to interest many scholars and students. As arenas in which diverse processes are seen to coexist and interact, regional geography will continue to shape the field's intellectual trajectory as well as popular interest in matters geographical.

REGIONAL GOVERNANCE

The concept of regional governance refers to a mode of self-regulation that incorporates both public and private actors' strategic planning and regional development initiatives. The approach is linked to the late modern transformation of statehood and can be understood as a reaction to state and municipal deficits in governing. Although the term has its origins in Britain, the phenomenon can be observed in many other Western countries, such as the United States and Germany. For this reason, it is appropriate for geographical research to focus on international comparisons of regional development strategies, evolutionary pathways, and conflicts.

Criteria of Regional Governance

In recent decades, large-scale societal changes have radically undermined the idea of a strongly intervening nation-state. As the nation-state has been gradually displaced as the center of regulation, new centers of power have emerged at the supranational and subnational levels. The concept of regional governance denotes the shift of governance to the subnational level. It emerges where national policies lack suitable implementation and where specific regional institutions are necessary for developmental solutions. In addition, regional governance emerges where problems exceed their local borders and where conventional modes of regulation turn out to be not adequate.

Regional governance must be analytically distinguished from regional government. While the

latter refers to state institutions, formal rules, and practices to administrate political subdivisions, regional governance relates to a mode of self-regulation in which regional problems are treated by cooperative actors operating at a regional level. This view incorporates both public and private actors into a pluralistic network that results in “multi-actor level play.”

Since regional governance involves actors from different political subsystems, the strategy for encouraging cooperation has been changed. Besides intrasystemic relations (e.g., intermunicipal cooperation, strategic alliances, and public engagement), other types of intersystemic interactions (e.g., public-private partnerships, corporate citizenship, and public participatory channels) become increasingly prominent. Thus, the term *regional governance* refers not to an entirely new phenomenon but to a group of large changes that appeared during the past decades. Regional governance represents the reality of complex interdependencies and interactions among numerous institutions. It refers to a comparatively loose coupling of participating stakeholders acting voluntarily.

Although regional governance is characterized by direct and flexible interplay, the establishment and consolidation of a minimum of institutional capacities are nevertheless central preconditions. As those institutions may differ regionally, certain governance arrangements may be more effective than others. In many cases, a core is constituted that canalizes interactions, minimizes transaction costs, and increases the reliability of expectations. In doing so, the organizational core forms the “administrative infrastructure” but without formal bureaucratic procedures. In addition, a charismatic leader often presides over the organizational core. Because of the power to integrate the actors of different proveniences, such leaders are essential for regional cooperation to succeed.

In analytical terms, regional governance can be characterized by changes in the logic, principles, and instruments of governance. A shift from state-centered, top-down interventional strategies to bottom-up and network-like strategies of regional actors becomes increasingly apparent. Thus, state control and coordination are displaced by public and private cooperation, and

the state’s instruments of regulation (e.g., licensing procedures, regional policy) are increasingly accompanied by communicative processes (e.g., moderation and mediation).

Regional governance structures have many advantages. For example, they promote intersystemic communication, typically through meetings and discussions for various political and administrative actors; private actors can profit from direct access to political decision makers. Due to these collective efforts, which exceed any individual actor’s ability to act, synergistic effects become possible. Furthermore, regional governance may initiate learning processes (e.g., best practices) as well as conflict management.

Addressing the advantages, however, does not deny the possibility of governance failure; in critical situations, actors can refuse to participate in a governance network. It is even more problematic when actors with very different interests block decision making or establish competing interconnections. This problem may cause a lack of trust and lead to frustration. As a consequence, governance failure may endanger the competitiveness of regional regimes.

Therefore, many efforts have been made to integrate actors into regional governance structures. These efforts include professional communication strategies as well as regional image and identity campaigns. To minimize the possibility of a governance failure, these initiatives are intended to establish loyalty, solidarity, and responsibility for the entire region. For this reason, it is not only formal institutions and organizations that guarantee successful regional governance; “soft” politics of persuasive control also are significant.

Regional Governance in the United Kingdom

Although persuasive control can contribute to successful regional governance, it may also be used by interest groups seeking to prevent the implementation of certain policies. This obstacle is particularly obvious in the development of governance structures in British regions. Against the backdrop of a comprehensive reform of Britain’s government in the 1980s, there have been many attempts to decentralize and regionalize the country’s regional policy (“devolution”). This trend occurred not

only because of Celtic efforts for greater autonomy in Scotland, Wales, and Northern Ireland but also due to European Union (EU) integration. To allow for the implementation of EU policies, a regional level was essential for the United Kingdom.

The regional level of governance has traditionally been rather weak in the United Kingdom. When it took over the government in 1997, the Labour Party initiated a systematic shift of executive and legislative functions from the national state to the regional level. This shift primarily benefited the Celtic regions, where the new Scottish parliament and the Welsh and Northern Irish national assemblies developed proposals across various fields of policy (i.e., education or health care in the Scottish parliament). Accordingly, decentralization and regionalization have also been discussed for the English regions, which led to the attempt to establish regional governance structures in the English regions. The aim was to set up the organizational framework for regional development strategies and, thus, to activate a regional level of governance.

As this example shows, the establishment of a regional governance level has not been an easy undertaking. In northeastern Britain, for instance, an economically driven movement to resist policy devolution has been established to prevent the implementation of regional governance structures. The resistance was ignited by attempts to establish so-called regional assemblies to ease municipal administration as well as to advance the control of the Regional Development Agencies' activities. The critique focused on the implementation of an additional bureaucratic barrier and the presumed waste of taxpayers' money it would foster. By means of that persuasive argumentation, the northeastern opposition was able to mobilize its supporters and defeat the proposal for regional assemblies.

Despite the difficulties of decentralization and regionalization, regional governance is still a major concern in political and academic discussions. However, regional governance is increasingly connected to metropolitan-wide development issues. So far, the academic discussion has largely been centered on the United States and the European continental-wide debate about regional governance. The focus lies on the development of coherent metropolitan forms of governance that have been created using a diversity of actors.

Regional Governance in the United States

In the United States, political and academic concepts dealing with the reform of governance at the metropolitan level were developed relatively early. The two dominant paradigms (metropolitan reform and public choice) have concentrated on actors and structures within local political and administrative institutions as well as socioeconomic developments at the municipal level. Initially, metropolitan reformers focused on the question of appropriate formal institutions for governing metropolitan conglomerations. They attempted to find institutional solutions for balancing diverse functional demands with local political borders. In contrast, advocates of the public choice concept focus on the optimal satisfaction of needs by multiple cities, emphasizing the advantages of the efficient allocation of common goods as an incentive to promote interurban competition.

Similar to academic research, the current governance discussion is focused on metropolitan issues. Distinctive patterns of sociospatial segregation, urban sprawl, and the attempts to develop competitive but sustainable urban development strategies constitute a significant stimulus for consideration of political and academic governance. In contrast, however, the new concept of governance concentrates on the political and administrative system of major urban agglomerations or on regional resource allocations. Against the backdrop of late modern political, administrative, and socioeconomic changes, processes of local self-regulation are analyzed in terms of their feasibility.

Although the term *regional governance* is not widely used by politicians or political scientists in the United States, there are parallels to the British debate about regional governance and the corresponding concepts of "city regions." In the United States, however, the discussion centers on "metropolitan governance," "new (metropolitan) regionalism" or "urban regimes." This terminological shift may be ascribed to the dominant concepts of metropolitan reformers and public choice, where decision-making processes were in the foreground. The current discussion, however, concentrates on the cooperative and network-like interplay between political and economic actors

and civil society. Despite the similarities in research, the American debate appears more heterogeneous. Depending on the way one looks at the issue, different theoretical foci (e.g., neoinstitutionalism) as well as different empirical contexts can be observed. The most sophisticated work is in a neo-Marxian tradition that analyzes the processes of political, administrative, and socioeconomic restructuring due to the transformation of global capitalistic accumulation as well as the rise of the neoliberal state.

Regional Governance in Germany

The German discussion of regional governance was a response to a fundamental economic weakness and the corresponding deficit in public finances. As a consequence, the social safeguards of the national welfare state came under pressure, and local strategic planning and regional development were needed to ameliorate predicaments set into motion by these national changes. The necessity of enhancing the economic growth potential of major urban agglomerations was highlighted in the 1990s. Furthermore, a discussion about self-regulation was initiated to mobilize metropolitan self-empowerment as well as interurban competition without using additional national financial assistance.

The concept of European metropolitan regions represents the attempt to stimulate competitive political and economical practices. Meanwhile, 11 metropolitan governance regions have emerged, and the ability to stimulate cooperative interplay among the different local actors became the most important precondition for their formation. In many cases, the metropolitan areas show an organizational core that coordinates diverse territorial actors. The federal state, which has played a traditionally intense role, has now become a *primus inter pares* and does not intervene very much in regional self-regulation processes.

With regard to theoretical and empirical research, regional governance has been analyzed by both political scientists and geographers. Researchers focus on questions concerning regional actor network structures (polity), their contents (policy), and the modes of operation (politics). This work uses various perspectives,

including control theory, neoinstitutionalism, structuration theory, and Luhmann's theory of social systems, which emphasizes communicative intra- and intersystemic interactions.

The critical point is that regional governance is not a silver bullet to solve problems of modern societal regulation. Although the formation of regional governance structures may open up the potential to act, which was limited by the nation-state, empirical studies often show that regional governance has its own problems in achieving efficiency as well as legitimation. For this reason, it is fruitful to consider normative aspects when dealing with regional governance.

REGIONAL SCIENCE

Regional science is among the youngest of the social sciences. This introduction to regional science covers its definition, history, topics, and methods.

Definition

According to its founding father, Walter Isard, regional science uses diverse combinations of analytical and empirical research to study social problems with regional or spatial dimensions. While major concerns of many social disciplines involve regional or spatial dimensions, regional science exhibits a multidisciplinary aspect in both its research topics and its research methods. Accordingly, scholars in regional science, called “regional scientists,” may be educated in the disciplines of regional science, economics, demography, political science, sociology, geography, civil engineering, urban planning, law, and public policy, among others. Due to this multidisciplinary feature, regional scientists have experienced difficulties in delivering a widely accepted definition of regional science. Nevertheless, Walter Isard has suggested three indispensable components of regional science: regions, social issues, and science.

Regional science focuses primarily on regions. A region might be a county, a city, a group of counties, a state, or a megaregion involving more than one state. It is generally a geographic unit smaller than the nation in which it is found. Regional science also concerns social issues. Unlike Earth scientists or physical geographers interested in physical attributes on Earth’s surface, regional scientists focus on human activity or social issues in a region and address interactions between

human beings and the region where they are located. Last, regional science is labeled as science. Regional science not only borrows scientific methods from the disciplines of mathematics, economics, and statistics, as many other social sciences do, but it also develops its own analytical tools (e.g., spatial statistics and spatial econometrics).

History

Social scientists have been studying regions for a long time. Early influential work in regional science includes agricultural location theory, developed by Johann Heinrich von Thünen; industrial location theory, developed by Alfred Weber; and central place theory, developed by Walter Christaller and August Lösch, all of which are part of location theory, which addresses factors affecting the location choice of economic activity. In the 1940s, some social scientists, led by the MIT economist Walter Isard, felt that the importance of regions in the social sciences was inadequately addressed and thus endeavored to build a research field as well as a scholarly association that focused on the interactions between human beings and regions. The launch of the Regional Science Association in 1954 signified the formation of a multidisciplinary field, “regional science,” and enabled better codification of methods and exchange of ideas among economists, geographers, sociologists, statisticians, and urban planners.

Regional science was recognized by a large number of social scientists soon after its formal establishment in the 1950s and experienced a remarkable expansion thereafter. Several path-breaking publications drove the development of regional science and fostered its international acceptance as an independent yet interdisciplinary research field. Brigitte Waldorf identifies *Location and Spatial Economy* and *Methods of Regional Science* by Walter Isard, *Location and Land Use* by William Alonso, *Entropy in Urban and Regional Modeling* by Alan Wilson, *Spatial Econometrics* by Luc Anselin, and *The Spatial Economy* by Fujita et al. as important books central to regional science. The growing influence of this research field paralleled the international expansion of the Regional Science Association

(renamed as the Regional Science Association International in 1990). By 2008, it consisted of more than 4,000 scholars from all over the world and has developed into the umbrella organization of three supranational organizations, North American/Americas Association, the European Regional Science Association, and the Pacific Regional Science Conference Organization, which further oversee many subnational, national, and cross-cutting, language-based regional science organizations (e.g., the Western Regional Science Association in the United States; the French Section, the German Section, and the Nordic Section in Europe; and the Japanese Section in Asia Pacific). The two decades following the establishment of the RSA also saw the creation of academic programs in regional science in some universities, notably the University of Pennsylvania, Cornell University, and the University of Illinois at Urbana-Champaign. Graduates from those programs later became the leading scholars in regional science—for example, William Alonso, Masahisa Fujita, and Luc Anselin. Meanwhile, journals focusing on regional science were founded, including *Papers in Regional Science* (1955), *Journal of Regional Science* (1958), the *Annals of Regional Science* (1967), *Regional Science and Urban Economics* (1971), and *International Regional Science Review* (1975). These journals contributed considerably to the development of the regional science field.

Regional science entered its mature years in the 1990s. The replacement of “thinking regionally” with “thinking globally,” beginning in the 1980s, witnessed the stabilization of expansion of regional science and the closure of several regional science programs in universities, for example, the first ever and flagship regional science department at the University of Pennsylvania. Not being a “foundation discipline” organized along traditional academic lines, regional science has faced difficulties in being identified as an indispensable academic field. Nevertheless, regional scientists (e.g., Scott Loveridge) are still optimistic about the future of regional science, given the growing popularity of understanding regional change and the technical improvement particularly in geographic information systems and spatial econometrics through which regional models and data can be better married.

Topics

Regional science may cover a wide array of topics, given that social issues exhibit spatial or regional dimensions. Regional scientists nevertheless distinguish themselves from other social scientists by putting regions at the center of their attention. Walter Isard argues that economists pay only peripheral attention to regions, while their key concerns are more likely to be investment, employment, price, tax, trade, and other economic indicators of the regional system. Scott Loveridge identifies six classic regional science “questions”:

1. What are the determinants of industrial location?
2. What are the regional economic impacts of the arrival or departure of a firm?
3. What are the determinants of internal migration patterns and land use change?
4. What factors influence regional specialization and exchange?
5. What are the potential environmental impacts of social and economic change?
6. What are the geographic associations of economic and social conditions?

While those classic questions, together with the new development of regional science, suggest many topics, the major concerns of regional scientists can be traced from those classic regional science publications, including a focus on issues of economic and social aggregates and disaggregates across spatial units.

Regional science was created primarily out of the traditions of location theory. Walter Isard developed a mathematical formulation (similar to that of production theory) that addressed the most traditional location theories, centering on Johann Heinrich von Thünen, Alfred Weber, and August Lösch. He highlighted the central role of transport in determining locational equilibrium in economic activity. Walter Isard also built modern location theory by introducing industrial complex analysis into traditional location theory as a determinant of location choice and an expression of the interdependence of firms.

While Walter Isard focused on location theory of business, his student William Alonso addressed the pattern of residential land use in the urban context and laid the foundation for urban economics. Assuming all employment in the central business district (CBD), he argued that the incentive for a household to move farther from the CBD lies in the lower commuting costs rather than the usually marginal land cost savings. Richard Muth expanded Alonso's model by considering the effect of income on household commuting costs. The evolution of the monocentric urban structure was further extended by Edwin Mills, who investigated the decentralization of jobs and residences and the formation of subcenters as part of his development of the new urban economics of the late 1970s.

Both location theory and traditional urban economics are based on transportation costs. Such costs, especially the cost of moving goods, experienced a significant decline during the 20th century. This change challenges the theoretical base of classic regional science. In this context, there has been a growing concern over agglomeration among regional scientists. Nevertheless, it is not a new concept, since many early regional scientists, including Alfred Weber, Walter Isard, and Edwin Mills, have been concerned with economies of scale and agglomeration effects. However, it becomes remarkably important when transportation costs arguably are no longer the dominant factor of location choices of firms and residents. Some urban economists, notably Jane Jacobs and Edward Glaeser, highlight the role of cities in fostering knowledge spillovers or human capital externalities, a different agglomeration effect from the traditional approach of transport cost savings. In addition, the new economy geography developed by Paul Krugman, Masahisa Fujita, and Anthony Venables explains agglomeration using not only traditional elements such as economies of scale, transportation costs, and proximity to consumers but also issues of choice and variety in a rather mainstream, economics-oriented framework.

The topics mentioned above may be studied within a region. Regional scientists are also interested in interregional flows of goods (trade) and population (migration). Besides applying traditional visions (e.g., comparative advantage theory

and the Heckscher-Ohlin theorem) to regional analysis, regional scientists also have their own views on trade. The interregional input-output model developed by Walter Isard is important in that context. The investigation of migration highlights the effects of both personal characteristics and locational characteristics on migration patterns. Among other topics, Amitrajeet Batabyal and Peter Nijkamp consider the environment as an increasingly salient part of regional science research. Not necessarily embedded into one specific social topic, spatial interaction modeling and spatial data analysis as methods play a central role in explicating the role of regional science.

Methods

Regional science methodologically uses various forms of quantitative analysis in a formal scientific procedure. As an interdisciplinary field with diverse topics, it borrows a variety of methods that have been used in other sciences or social sciences. Walter Isard's early work employs many ideas and techniques in economics, such as equilibrium analysis, profit maximization, and input-output analysis. The new economic geography may not be new in its use of agglomeration theory, but it is still considered as a path-breaking step in regional science, primarily because it resorts to mainstream economic models (e.g., the Dixit-Stiglitz model of monopolistic competition) and extends them into a regional context, particularly as they relate to growth, urbanization, agglomeration, and regional differentiation. Similarly, many other mathematical inferences used in economics can be widely seen in regional science publications.

Spatial data analysis has highlighted the importance of statistical and econometric methods in regional science. General statistical and econometric methods, however, do not necessarily work well in the regional context, as a result of the effects of spatial dependency and spatial heterogeneity. To solve this problem, regional scientists have made exceptional contributions to statistics and econometrics by developing spatial statistics and spatial econometrics. Methods in regional science also rely on concepts used in physics, for example, in the gravity model discussed by Kingsley Haynes and A. Stewart Fotheringham and in the entropy approach of Alan

Wilson, which have dominated spatial interaction estimation.

REGIONAL SCIENCE ASSOCIATION INTERNATIONAL (RSAI)

The Regional Science Association International (RSAI), according to its official Web site, www.regionalscience.org, is “an international community of scholars interested in regional impacts of national or global processes of economic and social change.” The following paragraphs briefly introduce its history, organizational structure, meetings, and journals.

Formerly known as the Regional Science Association (RSA), the RSAI was founded in 1954 in the United States as a result of the then MIT-based economist Walter Isard’s efforts to draw together multidisciplinary social scientists, whom he called “regional scientists,” to analyze interactions between human beings and regions. Isard served as the first president of the RSA. With its expansion all over the world, the Regional Science Association was renamed as the Regional Science Association International in 1990. As of 2008, the RSAI and its member organizations consisted of more than 4,000 scholars from disciplines of economics, sociology, demography, political science, geography, civil engineering, urban planning, and public policy, among others.

Structurally, the RSAI has developed into the umbrella organization of three supraregional organizations: (1) the North American Regional Science Council (NARSC) before it expanded to the Regional Science Association of the Americas

by including the Brazil and Chile sections in 2008 and the Colombia section in 2009; (2) the European Regional Science Association (ERSA), and (3) the Pacific Regional Science Conference Organization (PRSCO). Each of these three organizations further oversees some national, subnational, or cross-cutting, language-based regional science organizations. The NARSC or the Regional Science Association of the Americas serves as the umbrella organization of the Mid-Continent Regional Science Association, the Northeast Regional Science Association, the Southern Regional Science Association, and the Western Regional Science Association in the United States and other regional science associations in Canada, Brazil, Chile, and Colombia. The ERSA oversees the British and Irish Section, the German Speaking Section, the French Speaking Section, the Nordic Section, and the Portuguese Section, among others in Western, Central, and Eastern Europe. Members of the PRSCO include regional science sections based in Australia and New Zealand, Bangladesh, Western Canada, Indonesia, Japan, Korea, Malaysia, Mexico, and Taiwan. Membership in these supraregional organizations is still expanding.

The RSAI and its member organizations hold conferences regularly. The first meeting was held December 27–29, 1954, in conjunction with annual meetings of the American Economic Association and some other organizations in Detroit, witnessing the birth of the RSA. With the structural changes in the RSAI, meetings today occur at different levels. The RSAI has been organizing its World Congress every 4 yrs. (years) since 1980. At the middle level, the NARSC meeting and the ERSA Congress are held annually, in contrast to the PRSCO conference, which meets every 2 yrs. Most national, subnational, and language-based members of these three supraregional organizations have their own regular meetings.

There are several journals associated with the RSAI. The official journal of the RSAI, *Papers in Regional Science*, also known as *Papers of the Regional Science Association*, was first published in 1955. Many sections of the RSAI also have their own journals, but only the *Annals of Regional Science*, the official journal of the Western Regional Science Association, involves a commercial publisher. Other regional science journals, though not directly linked to any regional science

organizations, are mostly founded and edited by members of the RSAI. For instance, *Journal of Regional Science* and *International Regional Science Review*, both founded by Walter Isard, are among the core journals of regional science and have earned their reputation even beyond regional science.

REGIONS AND REGIONALISM

Regions are a means for geographers to classify, categorize, or simplify Earth's surface. A primary concern of geography is how and why one part of the Earth is different from other parts. Given the vast size and variety of environments, both natural and human, on Earth's surface, it is practical for geographers to divide the Earth into more manageable pieces. Regions are tools that allow geographers to focus their inquiries onto manageable areas. The division into manageable pieces extends from global to very local scales, since regions may be as large as continents and as small as neighborhood blocks.

Regions are based on a commonality, sameness, similarity, or homogeneity. The homogeneity may be based on characteristics of the physical environment (climate, vegetation, or landforms), on human cultural traits (religion, language, settlement, economic activity, and ethnicity), or on a synthesizing combination of both physical and human elements. The key concept is that regions share common properties that differentiate them from each other. Regions can be considered to maximize their commonality within themselves and maximize their differences among one another. To accomplish that goal, regions have

both relative and specific locations, areal sizes, and boundaries or borders. Borders of regions may be absolute and concrete or may be transitional or gradual. Regions can even have transitional areas between other regions.

Regions are to geographers as eras are to historians. Just as historians categorize the past into eras or periods, geography and geographers categorize Earth into regions on the basis of commonalities in cultural traits such as religion, language, and ethnicity and in physical traits such as climate. Geographers from Carl Sauer to John Fraser Hart believed that one of the principal purposes of geography is to learn about regions and why they differ from each other. According to that school of thought, regions are based on how people have lived on the land, used resources, and interacted with their environment through time. Many schools and universities offer an introductory geography course, often titled “World Regional Geography.” Such courses typically cover the entire Earth during an academic term. In world regional geography courses, the planet is usually divided into the seven major regions of Europe, North America, Latin America, sub-Saharan Africa, East and southeast Asia, South Asia, North Africa and the Middle East (or West Asia), and Australia and Oceania. Additionally, those regions are often taught in separate regional geography courses. The key concept is that the areas within those regions share commonalities in terms of physical and human geography. The purpose of those courses, from global to regional, is to explain how and why regions differ from each other. For example, areas within North Africa and the Middle East are alike with respect to climate, religion, and languages, which differentiate them from other regions such as Europe or sub-Saharan Africa.

Additionally, many colleges or universities offer courses in systematic geography (often named “human geography” and “physical geography”). Human geography courses take a systematic approach in the study of worldwide patterns of language, religion, population, and other human traits and activities. Regions are also covered in these courses. For example, Europe is a region of Indo-European languages. Within this region of languages, there are subregions of Romance and Germanic Languages, and within

the region of Romance Languages rest regions of Spanish, French, and Italian. Within an Italian-speaking region, there are regional dialects that can be mapped, creating more regions. Courses in physical geography make use of the concept of region in showing different regions of climate, vegetation, and landforms. With regard to climate regions, the Köppen system, which creates climate regions based on vegetation, temperature, precipitation, and seasonality of precipitation, is perhaps the best known. The Köppen system recognizes tropical, temperate, continental, polar, and dry climate regions. The goal in these systematic courses, whether human or physical, is, for example, to explain why there are different regions of language and climate.

Functional Regions

Functional regions are usually based on an economic or civil activity within a delineated area. Media markets, sales territories, and school districts can be considered functional regions. Urban systems with a large metropolitan area and a hinterland of suburbs and rural areas form a type of functional region based on the functional properties and relationships between the city and hinterland. Often these regions are cobbled together from existing political jurisdictions. Metropolitan Statistical Areas created by the U.S. Office of Management and Budget are based on county boundaries. These regions consist of the counties housing a large central city, its suburbs, and a rural hinterland. Functional regions are more limited in their chosen characteristics, since they function as regions for a particular purpose. The practice of creating functional regions for planning or for jurisdictional purposes can be considered regionalism.

Regionalism

Regionalism can refer to the practice of creating regions in a country or political jurisdiction for management, planning, and governance. Regionalism can also be considered a philosophy or method for solving problems by employing the concept of region. Regionalism, related to the field of regional science, often seeks mathematical, statistical, and formulaic approaches employing the scientific method as closely as possible in

answering questions and tackling issues such as economic or social inequality between regions. Park districts, school districts, or transportation authorities created by combining local governmental jurisdictions are examples of regionalism. Metropolitan councils, which provide governance or planning for multiple municipal jurisdictions, are formed to provide more efficient governance, public services, and planning. The theory is that integrated metropolitan councils can more efficiently solve problems and take a larger regional view benefiting the entire region instead of satisfying more parochial interests. At larger scales, the Tennessee Valley Authority (a congressionally created, multistate public utilities and emergency services provider in the southeastern United States) and the European Union are also examples of regionalism. Regionalism can be synonymous with regional planning or regional development.

REGULATION THEORY

Regulation theory emerged in France during the 1970s as an extension of Marxist political economy. The theory is especially associated with ideas developed in Michel Aglietta's seminal book

A Theory of Capitalist Regulation (1976). In its basic form, regulation theory posits that when capitalism changes over time, new institutions develop to support the prevailing economic system. These clusters of economic and political institutions form distinct societal paradigms during separate phases of capitalist development.

The historical background to regulation theory is the tumultuous end of the 1960s, with its social upheavals and growing economic uncertainties—a period when the capitalist economy appeared weaker than at any point since the Great Depression. However, a decade later, it was clear that capitalism would not disintegrate due to its inherent contradictions, as orthodox Marxism suggested. In fact, it proved to be quite resilient. Faced with an economic and political crisis, capitalism was capable of “reinventing” itself by relying on new industrial organization, new global strategies, and a rethinking of state economic policies. This reinvention process, according to regulation theory, involved a change in the *regime of accumulation*—the transition from Fordism to post-Fordism. A regime of accumulation aims to create a stable relationship between consumption and production. It outlines the basic economic relationships in society, such as the conditions of production, private and public consumption, savings and investment, and the general scope and proper role of government. The specific social and economic institutions, cultural norms, and major government policies that must be in place and work together in a coherent fashion to support the regime are collectively referred to as a *mode of regulation*. These ideas in regulation theory draw, at least implicitly, on the concept of a “social contract” that emphasizes the idea of underlying informal agreements in society, providing common rules for cooperative behavior between groups and individuals. A mode of regulation is an outcome of collective action, political decisions, and various semi-independent variables, such as technological change; therefore, it involves periodic adjustment of the procedures and institutions.

Fordism and Its Demise

More specifically, regulation theory outlined how Western capitalism was organized after World

War II and how large societal institutions were crucial for the particular regime of accumulation called Fordism. The term *Fordism* has Gramscian roots, but it was expanded and popularized by regulation theory and remains one of its most enduring concepts. On the production side, the Fordist regime was associated with assembly-line-style mass production. Just as Henry Ford's story tells us that his company paid his workers above the industrial wage at the time so that they could purchase the automobiles they produced, it became the goal of the state to institute a consumption norm for the good of the overall economy. Raising the wages and living standard of the working classes became not only a moral but also an economic imperative. The Fordist consumption norm was mainly a demand-led approach used to generate markets for new products and services. Consumption was underpinned by a mode of regulation that included high union-negotiated wages, the welfare state, social security, and government loan guarantees, ensuring high consumption levels. A far-reaching compromise existed in a tripartite power structure: business, labor, and government. This description of recent economic history is not unique to regulation theory; however, it synthesized multiple events and policies into a well-articulated "grand theory."

The mode of regulation as described here was not identical in all countries or regions. The mass consumption model was best developed in the United States, while the labor relations model was taken further in Western Europe. The Fordist social contract in many European countries (particularly Scandinavia) was deeper and more comprehensive than in the United States. The role of labor unions was more institutionalized into a corporative political system, where wages were determined by national negotiations. Even the political decision-making system integrated the different participants of the labor market. Although under pressure, the model remains partially in place in Western Europe today. In the United States, the right to unionize was established by federal laws starting in the 1930s, but the laws also allowed for the development of "peripheral Fordism" through right-to-work provisions adopted by some, mostly southern, states. The term *peripheral Fordism* originally referred to the labor-intensive economies of Southern

Europe, but it has similarly been used to describe regions such as the North American South, which were not quite ready, politically and economically, to fully embrace the emerging mass consumption model and its accompanying social relations. Nevertheless, many institutions of Fordism were national in scope, and the expanding Fordist government became a geographic equalizer of wealth.

In the late 1960s, Western economies suffered a slowdown, which was not simply an economic crisis caused by the latest business cycle or other problems solely within the economic realm. According to the regulation school, the relationship between political regulation and accumulation was out of sync, leading to a more deep-seated crisis. The contradictions of the Fordist model became increasingly evident. The rigidly negotiated wages accepted in the name of expanded consumption became counterproductive, creating a major rift in the labor-management compromise. As gains in wages and influence are not easily surrendered, labor conflicts compounded the existing problems. Economic decline created a search for new forms of institutions and policies, best exemplified by the conservative revolutions of Ronald Reagan and Margaret Thatcher.

The Nature of Post-Fordism

Fordism is generally considered by regulation theorists to have been replaced in the late 20th century by a new regime referred to as *post-Fordism*. Its nature is not fully realized, and researchers often stress the unpredictability of regime formation. Some prefer not to proclaim it a regime, only a "disorganized form of capitalism" that has emerged after Fordism and is guided by few principles other than market dictates. More recently, the term *neoliberalism* has been widely adopted instead of post-Fordism, which indicates a general dissatisfaction with regulation theory among many geographers. (For consistency's sake, however, the term *post-Fordism* is used throughout this entry.)

From the economic-geographic perspective, no single coherent system characterizes the post-Fordist industrial sector, although fundamental changes in the way production is organized have occurred. Flexible specialization provides a clear alternative to Fordism, with its craft-style, small-batch

production localized in certain industrial districts. However, it has not become the all-encompassing principle of industrial organization. Nor has the Japanese-inspired just-in-time production or European industrial organization, which has retained some of its Fordist character with its strong collective agreements. This lack of coherence has led to valid concerns about the viability of post-Fordism as a concept in industrial geography.

Moreover, in an era of global capitalism, the old national Fordist institutions are less effective. The transition to post-Fordism has found support in monetarist/supply-side policies in the wake of an economic crisis that the old macroeconomic model—Keynesianism—could not predict, explain, or cope with. Adjusting the deficiencies of the market is now attempted by encouraging supply instead of demand, through lowering taxes, deregulation, reducing inflation, and curbing government spending. The result is the subordination of social policy to economic growth incentives based on competitiveness and innovation.

Regulation theory interprets this as a realignment between economic policy and the emerging logic of capitalism. Economic policies have had the intended effect of increasing profits. Corporate management considers its overwhelming responsibility to be the accumulation of profit for shareholders, not necessarily adherence to a pattern of sustainable growth. Therefore, the new capitalism of hyperaccumulation appears less concerned with long-term goals and more interested in instant monetary gratification. The question is what constitutes a mode of regulation in such a system. Regulation theory has been vague on that issue, but the answer may lie in a rescaling process and changes to the territorial mode of regulation.

Although a process of economic nationalization took place under Fordism, economic geographers argue that post-Fordist competitiveness is based on local or regional conditions. Together with the aforementioned globalization, the outcome is a so-called hollowing out of the national state, which leaves more power in global, regional, and local hands. The responsibility for accumulation of supporting functions (ideological, reproductive, or production oriented) is particularly divested to the local level. If power devolves, the federal government has less capacity to implement the

policies that characterized the Fordist regime. Instead, there is a role for the local state in building new institutions to support education, infrastructure, and public-private policy interaction that, perhaps, represents emerging local modes of regulation. Such a turn of events has moved regulation theory closer to urban geography and away from its macroeconomic origin.

Critique of the Theory

Over time, empirical and theoretical work based on the regulation school has altered and extended the original propositions. Aglietta's hypothesis of what comes after Fordism was perhaps as good as anyone's at the time, but in retrospect, it was inaccurate. In light of almost three decades of economic change, a series of valid concerns regarding the approach have emerged. Many have rightly pointed out that the theory was too focused on the manufacturing economy and especially on workplace relations. The postindustrial turn makes it necessary to rethink the mode-of-regulation concept. In fact, the central tenants of the regime argument have been detached from the manufacturing floor.

One of the most important critiques highlights the tendency of the theory to compartmentalize economic development into discrete time periods. In reality, regimes are processes constantly challenged and undergoing change, which means that they are not necessarily coherent, with sharp, detectable breaks, as regulation theory assumes. It has been suggested that a stable mode of regulation is the exception rather than the rule; and instead, regulatory failure and crisis are the norm. Moreover, assuming temporally distinct regimes has a tendency to reify the theory. Should post-Fordism, then, be interpreted as an uncoordinated system rather than a new, stable regime of accumulation? This interpretation elicits additional comments. First, it is doubtful whether the current and old societal paradigms should be judged by the same yardstick. It might be irrelevant that post-Fordism does not conform to the standards handed down by the earlier regime (if Fordism was, in hindsight, as monolithic and stable a societal paradigm as portrayed). From this viewpoint, regimes should be regarded as archetypes more than empirical absolutes because policy is always

complex, incoherent, and fragmented. If more power is placed in the “invisible hand” of the market, the same level of coordination is not possible. Society has embraced, even institutionalized, perpetual change, which is fundamentally different from the Fordist preoccupation with stability. Even if the critique of the sharp periodization of economic history is relevant, a regulationist would argue that current society is different enough from the past to render post-Fordism a useful concept.

An additional critical comment made by geographers is that the spatial scale of analysis is neglected. This criticism is pertinent to the original proposition, but much work has emerged since then. Although the nation-state was originally stressed as the locus for the formation of various modes of regulation, place-sensitive analysis has been growing. Lipietz’s notion of peripheral Fordism added a necessary international dimension to the theory. It has also been acknowledged that each locale has its own regime based on particular conflicts and compromises. Particularly, scholars from geography and social science disciplines other than economics have been more active in exploring the local implications of regulation theory. It is doubtful, however, whether much research explicitly using a regulation theory framework is forthcoming in the near future, as the concept of neoliberalism appears to be favored by those in critical urban and economic geography today. Instead, regulation theory remains a source of inspiration for much geographic research, but not as the dominant overarching theory.

RELATIONAL SPACE

See Relative/Relational Space

RELATIVE/RELATIONAL SPACE

In contrast to absolute space, which is fixed, asocial, and timeless, relative or relational space reflects the wide varieties of ways in which distance is measured and conquered, that is, space as socially made and remade over time. Relative space thus portrays geographies as fluid, mutable, and ever changing. (Some observers differentiate relative from relational space, while others treat them as synonymous; see quote by Harvey below.)

The genesis of relative space may arguably be traced to the famed 17th-century intellectual Gottfried Leibniz, Isaac Newton’s great rival in the invention of calculus and the founder of a perspective on spatiality sharply at odds with the prevailing Euclidean/Cartesian emphasis on absolute space. In contrast to Newton, who held that space exists independently of how it is measured or what it contains, Leibniz held that time and space are relative, that is, comprehensible only with reference to specific frames of interpretation. Distance, for example, may be understood only through appeal to the space between two or more objects situated in space. Relative space, however, remained subordinate to absolute space

for many years, at least until the massive changes of the Industrial Revolution reworked the meaning of spatiality itself.

Marxism, too, offered a surprisingly early vision of relative space, tying it to the historical process by which capitalism reached out and conquered new spaces, enveloping them within ever-broader spatial divisions of labor. Marx (1973) argued in the *Grundrisse* that

while capital must on one side strive to tear down every spatial barrier to intercourse . . . it strives on the other side to annihilate this space with time, i.e., to reduce to a minimum the time spent in motion from one place to another. (p. 539)

David Harvey's extension of Marxist analysis into geography, which drew on the influential works of Henri Lefebvre and initiated a simultaneous spatialization of Marxism, linked the construction and reconstruction of relative space to the endless search for ever-greater profits and outlets for surplus value. The need to "annihilate space by time" is thus fundamental to the operation and survival of capitalism on an ongoing basis, that is, its ability to reproduce itself at ever-expanded spatial scales and to accelerate temporal rhythms of capital accumulation. Harvey (2006b) offers useful definitions of *absolute*, *relative*, and *relational space*:

Absolute space is fixed and we record or plan events within its frame. This is the space of Newton and Descartes and it is usually represented as a pre-existing and immovable grid amenable to standardized measurement and open to calculation. Geometrically it is the space of Euclid and therefore the space of all manner of cadastral mapping and engineering practices. . . . The relative notion of space is mainly associated with the name of Einstein and the non-Euclidean geometries that began to be constructed most systematically in the 19th century. Space is relative in the double sense: that there are multiple geometries from which to choose and that the spatial frame depends crucially upon what it is that is being relativized and by whom. . . . The relational concept of space is most often associated with the name of Leibniz who . . . objected vociferously to the absolute view of space and

time so central to Newton's theories. His primary objection was theological. Newton made it seem as if even God was inside of absolute space and time rather than in command of spatio-temporality. By extension, the relational view of space holds there is no such thing as space or time outside of the processes that define them. . . . Processes do not occur *in* space but define their own spatial frame. (pp. 121–123)

Similarly, Anthony Giddens's (1984) structuration theory portrayed relative space in terms of time-space distancing, the "stretching of social systems across time-space on the basis of mechanisms of social and system integration" (p. 377), as "disembedding mechanisms" such as symbolic systems and transportation technologies allow social interactions to extend across ever wider time-space distances.

Kern's famous book *The Culture of Time and Space 1880–1918* addressed the changing meanings of spatiality in the midst of late-19th- and early-20th-century social and technological changes. Wave upon wave of innovation altered the capacities of people to defeat the friction of distance, to interact with one another, and to learn about distant places, leading to a widespread reconfiguration of notions of proximity. The telegraph, telephone, bicycle, automobile, and airplane, and impressionism, cubism, photography, cinema, and the theory of relativity, all served to blur conventional meanings of near and far, bringing into mutual contact peoples and societies that had long been isolated. This transformation rendered traditional views of distance, and thus absolute space, less meaningful and elevated the concept of space as a product of changing social circumstances.

The theory of relativity, prefigured by the great French mathematician of non-Euclidean geometry, Henri Poincaré, in the 1890s, included an outright rejection of absolute time and space as inherently, objectively "correct." Albert Einstein, with the special theory of relativity that he articulated in 1905, extended Poincaré's analysis by showing mathematically that the results of experiments with time and motion inevitably depended on the viewer's choice of space-time coordinate definitions, a conclusion with enormous repercussions not only for physics, cosmology, astronomy, and other fields but for

social analyses of space as well. Relativity views energy and matter as curving four-dimensional space-time so that it wraps around itself, forming a warped surface over which light rays glide. The measurement of time is predicated on the observer's location in space, his or her velocity relative to other places, and the gravitational mass that shapes the local universe. Thus, gravitational fields slow down the speed of light by warping space and time. Relativity repositioned time and space, suturing them to the materiality of the physical world by emphasizing how mass warps and stretches these dimensions around itself. Gravity, therefore, is not an independent force but the effect of warped space and time. Moreover, rather than existing independently of their contents, and thus extending equally throughout the universe, time and space are organized by the specifics of local matter and motion; with Einstein, the "now" became confined to the "here." Einstein argued that the dilation of time is generated by the relative motion between an observer and what he or she observes, a view that soundly rejects absolute time and space because absolutes could only exist if they were being measured objectively. Relativity thus implies a return from objective time and space to a vision that takes the individual observer as its point of departure.

Smith (2003) argues that the end of the colonial era in the early 20th century was marked by the pragmatic need to view space in relative rather than absolute terms. At this historical juncture, the scale of capital accumulation exceeded the boundaries of the nation-state, creating a problem that could only be solved through the spatial fix of global empire. For the first time, the expansion of one state was only possible through its incursion into the territories held by another. As a result of this state of affairs, no longer was it possible to conceptualize political problems and predicaments in isolation from one another, a cultural turning point that coincides precisely with the rise of modern geopolitics. The famed British geopolitical theorist Sir Halford Mackinder aptly captured this transformation in his analysis of the geopolitics of imperial rivalry, in which the seafaring hegemony of Britain would be challenged by the growing land-based power of Russia and its conquest of space through the railroad. In putting forth this view, he became perhaps the first theorist of the world as an integrated entity.

With the invention of the airplane, distance became increasingly trivialized, and as with the railroad, telegraph, and telephone, the experience of flying was regularly described as "annihilating space." Generally, the more rapid is the form of transportation or communication, the more intervening spaces disappear. Rapid time-space compression thus disembeds places in between, favoring origins and destinations at the expense of intermediate locales. Airplanes in this sense formed "worm-holes" through global time-space, paths in which locations en route ceased to exist or matter. Air travel could ignore the traditional physical and social barriers between places, rendering old divisions between land and water meaningless: Even islands such as Britain were effectively islands no longer. As flying became increasingly accepted among the public, distances between pairs of cities were conceptualized with increasing frequency in terms of hours rather than absolute distances.

The notion of relative space is central to the notion of time-space compression. Whereas absolute distances do not change, relative ones, as measured by travel time or cost, change constantly; given the rising transport velocities, in relative space, places draw closer to one another even as the absolute distance between them remains constant. For example, drawing on the famous example offered by Don Janelle, travel between Lansing and Detroit, Michigan, took approximately 1,300 min. (minutes) by stage-coach in 1840; by the 1870s, with the arrival of the steam locomotive, travel time had been reduced by two-thirds, to 180 min.; and with the introduction of the automobile, the journey was further reduced to only 80 min. Thus, while the absolute distance between the cities remained the same, the relative distance was reduced by 1,220 min. over 120 yrs. (years), or roughly 10 min./yr. In the 1960s and 1970s, as the impacts of space-adjusting technologies became clearer, relative space steadily gained in popularity, a shift accompanied, not accidentally, by the abandonment of logical positivism, with its fetishization of absolute space, and the move into a variety of relativistic epistemological views. Thus, relative space has an important epistemological counterpart in relativism more broadly: Just as space and time have been repeatedly folded, distorted, remade, reconstituted, and reinterpreted, there is no one,

single, “objective” viewpoint to which spatiotemporal reality presents itself.

In the contemporary historical moment, globalized, postmodern capitalism has given birth to complex geographies in which proximity and transport costs play relatively marginal or even insignificant roles. The airplane, satellites, television, and telecommunications, including the Internet, for example, have steadily led to forms of social interaction in which physical distance is rendered irrelevant. The result has been a series of convoluted landscapes marked by wormholes and tunnels, complicated spatialities of which globalization is the dominant but by no means only indication. Postmodern capitalism, thus, has elevated Leibnizian relative space to a historically unprecedented level of significance. Contemporary theorizations of relative space, marked by views such as actor-network theory and Doreen Massey’s power geometries, thus portray it in origami-like fashion.

In all these cases, ontological changes in transportation, communication, and representation have been accompanied by equally dramatic shifts in ideologies and ways of thinking. Modern science shook the doctrine of objectivism at its roots, substituting multiple times and spaces for the dominant Cartesian view hegemonic since the Renaissance, substituting new representations of diverse, fragmented realities and reordering the meanings of time and space. Relative space, in short, is a shorthand for the rapid declines in the friction of distance evident throughout the history of capitalism, industrialization, and modernity, one in which the significance of location does not disappear but is reconfigured along new and equally meaningful lines.

RELIGION, GEOGRAPHY AND

The geography of religion is a substantial subdiscipline of human geography that provides significant insight into the breadth and depth of religious traditions in their multifaceted contexts. The geography of religion involves the spatial study of religious systems and phenomena and includes a robust array of themes at numerous scales, including, but not limited to, religious diffusion, religious distributions, religious regions, religious diversity, religious fundamentalism, sacred space, religious landscapes, religion and the environment, and more recent developments in critical human geography.

Geographers of religion explore a multiplicity of faith traditions but tend to be more concerned with the social, cultural, and environmental associations of religion than with religion itself, though this is an internal point of debate among scholars. The geography of religion is therefore differentiated from religious geography, which, according to Petri Raivo, focuses instead on the role of religion in shaping human perceptions of the world and the place of humanity in the world.

The field is often described as the geography of religion and belief systems due to nuances and deficiencies in the term *religion*, which has no formally agreed on definition. The inclusion of belief

The city of Cuzco, Peru, with the Cathedral of Santa Domingo in the foreground. It was built on the site of Kiswarkancha, an Inca palace that was destroyed by the Spanish conquistadors. Completed in 1654, the cathedral is a UNESCO World Heritage site.

systems in the description of the discipline allows for a more inclusive study and permits investigation into phenomena such as civil religion.

The geography of religion has a strong institutional presence internationally, especially in the field of cultural geography, and is represented by formal groups of specialists in the United States, Germany, and Eastern Europe. Yet many scholars in fields such as religious studies or cultural geography, who are not overtly geographers of religion, also make important contributions to the field through research that is simultaneously religious and geographic.

Religious Diffusion, Distributions, and Regions

Traditionally, the geography of religion, as a sub-discipline of cultural geography, was especially concerned with the spatial nature of religious institutions and their material implications and characteristics across scales. Religions evolve through space and time and disperse across

geographical space through diffusion, migration, and competition for space. Religions diffuse in ways similar to those of other innovations, but they have unique modes of dispersion, including the migration of believers, contact conversion, and organized missions. Two key principles in the study of diffusion, carriers and barriers, apply to the diffusion of religion: Anything that moves must be carried, and the rate at which it moves is determined by what gets in its way.

Religions tend to exist within ranges and territories. Hence, mapping and understanding patterns of adherence is a significant area of study. A challenge in this field involves the complexity of obtaining data on religious affiliations, particularly in nations where the government does not collect such information in a census. Another complexity involves issues of aggregation and disaggregation, which are highly prone to the ecological fallacy.

Religious distributions have been reported in atlases and textbooks for more than 500 years through maps produced by Christian theologians, who describe religious hearths and borders.

The Yamunotri Temple in the Indian Himalayas. One of the four sites on the Char Dham pilgrimage, it is visited by Hindu pilgrims from across South Asia.

Source: Wikimedia Commons, http://en.wikipedia.org/wiki/File:Yamunotri_temple_and_ashram.jpg.

However, this does not mark the beginning of the field. One of the first major regional geography texts was written by Al-Muqaddasi, an Islamic scholar who, in AD 985, authored an important atlas with significant religious content. A contemporary dimension of the geography of religious distributions involves mapping religious regions and determining local denominational or religious predominance. In the United States, this task is accomplished by mapping aggregated county-level data. These studies can then be analyzed to determine religious diversity and other patterns of distribution in the local or regional religious mosaic. Most of the published studies of this type have occurred in India, Britain, and the United States, with Wilbur Zelinsky's work remaining the most well known. Zelinsky described the cultural regions of the United States, with a particular emphasis on religion. His efforts made prominent

the Mormon cultural region in the United States, which is now considered one of the easiest religious regions to identify and map. Another important and more recent text in this field is Edwin Gaustad and Philip Barlow's *New Historical Atlas of Religion in America*, which uses choroplethic aggregated county boundary maps of adherents to display the history and contemporary distributions of denominations in North America.

Sacred Space and Pilgrimage

Sacred places are locations deemed by believers to be particularly holy or sacred due to historical or ritualistic religious associations. In this sense, sacred space is contrasted with *nonsacred space*, which is described in the literature as profane space. Sacred places are, therefore, understood completely in terms that are religious by believers.

The Hajji Alija Mosque at Počitelj, in Bosnia and Herzegovina. Built in the 16th century, the mosque was destroyed during bombing by Serbian forces in 1993. The mosque and its minaret were later reconstructed.

Source: Michael Goodine.

Sacred places are frequently religious structures or artifacts, but they can also include natural entities such as rocks, hills, or trees. Geographers of religion explore many important questions involving sacred space, including why a particular culture deems a site as sacred and what implications such a designation has on the place and on the culture surrounding it. Related to this is the study of the

political power required to control a sacred site or the land surrounding a sacred place. Sacred sites are often at the heart of local, regional, or international conflict, as are the Temple Mount in Jerusalem and the Kashmir region on the borders of Pakistan, India, and China.

Belden Lane (2002) describes four axioms of sacred space: (1) “sacred space is not chosen, it chooses”; (2) “sacred place is ordinary place, ritually made extraordinary”; (3) “sacred place can be tread upon without being entered”; and (4) “the impulse of sacred place is both centripetal and centrifugal, local and universal” (p. 19).

A concept intricately linked with sacred space is pilgrimage. Pilgrimages are profoundly spatial, and so they are one of the more common and direct avenues of study in the geography of religion. *Pilgrimage* is defined as the physical traversing of distance to encounter a holy place and subsequently return to the point of origin. Pilgrimage is, then, a concept involving the circulation, rather than migration, of pilgrims, who promote the diffusion of ideas from religious nodal centers. Classification of pilgrimage is done through the identification of scale, frequency, and routes. Hindu, Jain, Mormon, Muslim, and Christian pilgrimages have been the major objects of study, especially in South Asia, Western Europe, and the Americas. In some circles, pilgrimage study is closely associated with the geography of

tourism, with the only distinction being the motivation for travel.

Religious Landscapes

Another important area of study in the geography of religion involves the impact of faith on the cultural landscape through architecture, centers of

worship, religious structures, cemeteries, place names, and sacred meanings given to natural phenomena. A theme common in cultural landscape geography is that landscape is a text or manuscript that can be interpreted to understand the cultural history of a locality. Cultural landscapes tend to be saturated with religious meanings that reproduce ideologies and connect landscape to other cultural phenomena such as regional or national identity. Landscapes can contain specific forms of religious phenomena such as domestic altars, roadside chapels, and church and temple architecture.

A field associated with religious landscape geography is the geographic study of cemeteries, known as *necrogeography*. As landscapes of death, graveyards are interpreted to understand the regional and communal attitudes, practices, and values of a culture. Specific areas of necrogeographic analysis include disposal of the dead, graveyard site selection, cemetery architecture and morphology, attitudes toward the afterlife, and residential segregation in cemeteries.

Religious taboos on food and wildlife can also produce an impact over space, as can religious belief in social norms such as dress, behavior, patterns of activity, and commerce. Food taboos can create sharp contrasts in agricultural practices within the same region. Similarly, work taboos that limit labor on certain occasions or in certain places affect the way land is used. Finally, religion affects landscape through place names, also known as *toponyms*, with religious associations to other sacred locations or saints.

Religion and the Environment

Nature and the environment have significant power to shape religious belief and practices. Likewise, a significant role is played by religion to influence worldviews and shape environmental attitudes and behavior, greatly influencing ecologies at scales from the local to the global. Some scholars even argue that religious value systems underpin the present ecological crisis. For instance, Lynn White traces the roots of the contemporary environmental crisis to medieval Christianity, which encouraged exploitation of resources based on the biblical command in Genesis to rule over the Earth and subdue it. Many Christian scholars protest this hypothesis, instead

interpreting the Bible as holistically mandating a stewardship approach rooted in caring for creation. Still, the hypothesis is indicative of the power of religion to affect the environment.

Recent Contributions

Newer cultural and critical geographic perspectives take into account the politics and poetics of sacred space, recognizing that the sacred is deeply interconnected with social and political dimensions. Sacred space is frequently contested space, and sacred spaces often lie at the heart of religious and secular conflict. Therefore, religious attitudes and symbolism are frequently part and parcel of political and ideological contestation across scales.

Other recent developments stem from theories concerning the social construction of identity. Religious identity is developed and sustained through the construction and maintenance of boundaries. Religion helps produce a sense of self and simultaneously a sense of community based on faith and belief.

Another recent development comes from the field of religious studies. Thomas Tweed's recent theory of religion, known as *crossing and dwelling*, employs spatial metaphors to understand religious flows moving through time and space, as religious individuals find their place by making homes and crossing boundaries. While Tweed is not a geographer of religion, his theory is profoundly geographic in nature, and many geographers of religion are using his work.

Conclusion

Religion is a significant factor in contemporary society, affecting the ways in which much of the world's population structure their daily lives. Geography is also a robust and integrative science, providing a helpful framework to study connections between religious practice and its implications over space. Therefore, the geography of religion shows no sign of waning in the near future. The field is varied in content and approach, has acquired increasing coherence in recent decades, and provides substantial insights into diverse religious traditions and their relationships with geographical contexts. The study of the

geography of religion will continue to be an important academic pursuit, albeit one that evolves with new internal approaches and developments in related fields such as religious studies and cultural geography.

RELPH, EDWARD (1944–)

Throughout his professional career as a geographer, Edward Relph has explored the nature and importance of places, landscapes, environments, and other taken-for-granted geographical dimensions of peoples' everyday lives. His books include *Place and Placelessness* (1976), one of the earliest and most accessible phenomenologies of place; *Rational Landscapes and Humanistic Geography* (1981), a powerful explication of philosopher Martin Heidegger's notion of *appropriation* as a potential vehicle for a lived environmental ethic grounded in respect and care for the natural world; and *The Modern Urban Landscape* (1987), an exploration of why modern cities look the way they do. The empathetic effort to see, describe, and understand everyday places and environments as thoughtfully and as thoroughly as possible is at the heart of Relph's geographic research and writings.

Born in 1944, Relph grew up in a small village in Southern Wales. At the University of London, he completed a bachelor's degree in geography in 1965 and a master's in 1968. He did his doctoral work in geography at the University of Toronto and in 1973 completed his dissertation, *The Phenomenon of Place*, which was revised and published as *Place and Placelessness* in 1976. From 1973 to the present, Relph has been a professor of geography in the Division of Social Sciences at the University of Toronto at Scarborough, a suburban Toronto campus.

During the 1970s, Relph became associated with humanistic geography. Like other geographers of the late 20th century, such as Anne Buttimer, David Ley, Marwyn Samuels, David Seamon, and Yi-Fu Tuan, Relph sought to move

geographic research away from objectified, measurable phenomena studied through positivist science and toward an understanding of geographical and environmental behaviors, experiences, and meanings as they could be interpreted through the Continental philosophical approaches of existentialism, phenomenology, and hermeneutics.

Of all the work in humanistic geography arising from this period, Relph's *Place and Placelessness* has had the most lasting influence because it explained, in simple but versatile language, why places are an integral part of human life and how their existential core can be described phenomenologically in terms of insideness—that is, the degree to which an individual or group feels a sense of belonging and attachment to a locale or environment, which thereby existentially is transformed into a place. In this sense, place gathers human worlds spatially and environmentally, marking out centers of human intention, meaning, and action that, reciprocally, help make place.

After *Place and Placelessness*, Relph continued to examine the existential and geographical aspects of place and its opposite, placelessness—present-day environments and landscapes of standardization, uniformity, and disconnection from human and environmental context. In *The Modern Urban Landscape*, for example, Relph considered how shifts in architecture, technology, planning, and social developments have been largely responsible for the changing physical appearance of Western cities in the past century. In *Rational Landscapes and Humanistic Geography*, he sought ways of seeing and understanding that might facilitate a gentle caretaking of places, people, and the things of nature—what Relph called an environmental humility. Relph (1981) argued that if the current human relationship with nature is to improve ecologically *and* existentially, the primary need is “for guardianship, for taking care of things merely because they exist, for tending and protecting them. In this there is neither mastery nor subservience, but there is responsibility and commitment” (p. 187).

Most recently, Relph has sought to clarify the conceptual and lived differences between spirit of place (the singular qualities of a particular landscape or environment that infuse it with a unique ambience and character) and sense of place (the synesthetic and largely unconscious facility of

human beings to feel and sense the uniqueness of a particular landscape or environment—i.e., its spirit of place). Relph has also probed what he calls a “pragmatic approach to place”—that is, a style of geographical reflection and practice that looks inward toward the uniqueness of particular places but also realizes that those places are integrally related to the larger-scale realm of other places and global interconnectedness. Relph argues that this mode of geographical understanding is crucial if humankind is to circumvent looming 21st-century challenges such as climate change, globalization, ethnic nationalism, and the depletion of inexpensive energy sources.

REMITTANCES

Remittances, in their most common usage, are the transfer of a portion of a migrant worker's wages back to his or her family. A more encompassing definition of remittances includes so-called social remittances: the sending of products (foodstuff, electronics, automobiles, etc.) and the transfer of ideas formed and beliefs adopted from migrant

Figure 1 Global remittance flows 2007

Source: International Monetary Fund. (2008). *Balance of payment statistics yearbook*. Washington, DC: Author.

destination workplaces to native communities. In this entry, *remittances* will refer to the simple monetary definition.

Remittances are an important geographic phenomenon due to the sheer volume and extent of monetary flow from more affluent to poorer nations and the fact that they are disproportionately received by poorer members of these developing countries. Such wealth transfer allows households to make important economic decisions concerning health, education, occupation, and daily living conditions. In many poorer nations, remittances have been shown to effect broadscale poverty and mortality reduction through increases in household income and better access to health care.

Geographic Explosion of Remittances

Prior to the 1970s, relatively little remittance income flowed among nations. Since that time, remittance transfers have increased dramatically in volume. Between 2000 and 2007, global remittance flows more than doubled, from \$132 billion to \$337 billion (Figure 1). The developing

world alone received \$251 billion in 2007. To put these numbers into perspective, Ireland's gross domestic product (GDP) was \$255 billion in 2007. Perhaps more important, remittances represent substantial contributions to overall GDP for many developing world economies. In 2006, remittances constituted more than 10% of the GDPs of 24 poorer nations.

Most world regions have received substantial remittance income. Latin America and the Caribbean received the plurality of remittance income (\$61 billion), closely followed by East Asia, with Europe and South Asia not far behind, in 2007 (Figure 2). On a per-country basis, India, China, and Mexico each received over \$25 billion in remittances in 2007 (International Monetary Fund, 2008). Lamentably, the area most in need of international assistance, sub-Saharan Africa, received only \$11.7 billion in remittance transfers in 2007.

Remittance Uses

The use of remittances is widely variable and highly dependent on the economic status of the

Figure 2 Regional remittance inflows 2007

Source: International Monetary Fund. (2008). *Balance of payment statistics yearbook*. Washington, DC: Author.

recipient household. Poorer households, especially those that practice subsistence agriculture, often use remittances for family maintenance, including diet diversification through the purchase of food grown off their farms. They are more apt to purchase medicines, improve the condition of their homes, and allow their children to spend more time in school. At times, when a household's primary breadwinner is away, remittances are used to contract agricultural workers to tend a household's land.

More economically stable remittance-receiving households have been criticized for the disproportionate use of remittances to increase their conspicuous consumption. It is common to encounter multilevel "trophy" homes in communities that receive large volumes of remittances. Other nonessential items purchased with remittances include packaged food, electronics, and high-end clothes and automobiles. There is also a strong expectation in many villages that migrants will host large celebrations on their return.

However, more affluent remittance-receiving households do not spend all their remittance

income on conspicuous consumption. Occasionally, remittance receipts are used to establish small businesses or to expand and improve the condition of farming operations. Additionally, they are used to pay for the construction of a parent's home or to fund the migration—often illegal—of other family members. And, just as with lower-income remittance recipients, a large volume of remittances is used to improve the education of children through the purchase of school supplies, placing children in private schools, and the financing of higher education.

Remittances as an Economic Diversification Strategy

Throughout much of the developing world, many households use remittance transfers as an economic diversification strategy. The most common type of remittance transfer is from migrant workers sending money from the developed world to a household in the developing world. Within-country urban-to-rural remittance transfers are also common.

There are a multitude of reasons for using migration and the sending of remittances as an economic diversification strategy. For families that have fallen on hard times, it is not uncommon to send one or more members to an economically more robust area to earn sufficient income to ride out the tough times. In many agrarian communities, the sending of migrant workers during slow periods of agricultural productivity, following crop failures, or to make ends meet between harvests is not uncommon.

Remittances and Development

It has long been argued that remittances have not lived up to their potential as catalysts for development in poorer countries. Many early studies on the topic concluded that the bulk of remittances are used for family maintenance and consumption rather than as seed money to start businesses. While it is indisputable that remittances fuel consumption, some argue that their delivery to poorer communities does spur development as they cycle their way through local and regional economies. Even when remittances are used to fuel conspicuous consumption, it is argued that secondary and tertiary recipients (local vendors and suppliers) of remittance income will use this infusion of money to create or expand their businesses, which will have a positive impact on local and regional development. As a final note, remittance income is also used to further the education of recipient household children and to reduce household poverty—both of which are certain long-term economic investments.

REMOTE SENSING

Coined in the 1960s by a geographer named Evelyn Pruitt, the term *remote sensing* refers to the collection of data about Earth's surface (and atmospheric) features or phenomena without being in direct contact with such features or phenomena. This entry first provides background on electromagnetic radiation (EMR), which is the information link that enables the collection of data about Earth's surface without being in contact with the surface. Next, the entry discusses sensors that capture EMR and are mounted on platforms (aircraft or satellite), which enables the remote collection of different types of imagery. Finally, the principles and strategies of image interpretation for extracting geographic information are covered.

There are advantages and disadvantages in using remote sensing technology for geographic research and applications, relative to more conventional, ground-based or in situ (i.e., direct) observation methods. The primary advantage is that remote sensing enables spatially continuous and contiguous, large-area sampling of Earth's surface and atmosphere. This means that data are comprehensive, synoptic (i.e., many features are observed simultaneously), and efficiently collected. Other advantages are the noninvasive, nondisturbing nature of sensing remotely and the ability to collect data for areas that are inaccessible or inhospitable for making observations on the ground. Often, historical information on geographic features or

conditions can only be derived through interpretation of archived imagery captured in the past. The main disadvantages of remote sensing are that remote observations are less detailed and precise and more uncertain than direct measurements made on the ground. Also, the sensing process, the image-processing steps, and the act of image interpretation all can yield more artifacts (i.e., false information) than would normally result when making in situ observations.

Electromagnetic Radiation: The Information Link

EMR is the important link that enables information about Earth's surface to be extracted. As the term suggests, both electric and magnetic fields are associated with EMR transfer, which can occur even in the absence of matter (i.e., in a vacuum). The orientation of the electric field determines the polarization of EMR. EMR travels at the same speed (the speed of light, or 300,000,000 m [meters] per second) through outer space and, effectively, through Earth's atmosphere, irrespective of wavelength or frequency. Wavelength and frequency are inversely related (i.e., short-wavelength EMR is high-frequency EMR).

All matter emits EMR, and the wavelength of emitted radiation is an inverse linear function of the temperature of the emitting material. A change in the electrical charge of matter, which can result from atomic-level changes in energy states or molecular-level motions such as vibration and rotation, causes EMR to be emitted. The sun emits shortwave radiation in an amount that is approximately equal to a *blackbody* (defined as a perfectly absorbing material that is in thermal equilibrium) having a temperature slightly less than 6,000 Kelvin. Earth's surface reflects incoming solar radiation (called solar irradiance) and emits long-wave radiation. The actual amount of radiation emitted by Earth surfaces also depends on the emissivity properties of different materials, which pertains to the efficiency of emission relative to a blackbody at the same temperature. Most of the EMR emitted by Earth surfaces is radiated within the thermal-infrared (TIR) part of the EMR spectrum at wavelengths ranging from 3 to 30 μm (micrometers), where $1\ \mu\text{m} = 10^{-6}\ \text{m}$.

Most remote sensing of the environment is based on passive imaging of solar reflective EMR, primarily in the wavelength range between 0.3 and 3.0 μm . This range includes the longer portion of the ultraviolet (0.3–0.4 μm), visible (0.4–0.7 μm), near-infrared (0.7–1.2 μm), and shortwave-infrared (1.2–3.0 μm) portions of the EMR spectrum. Passive optical remote sensors on aircraft or satellites capture EMR that reflects and/or is emitted from Earth surface materials and scatters off of or is emitted from atmospheric constituents. In most geographic applications, the surface-leaving radiation (called *exitance*) is the signal of interest, and the scattered or emitted atmospheric radiation is noise.

Solar radiation passes through the atmosphere in its path to Earth's surface and then, on being reflected, passes through the atmosphere again en route to a sensor on an aircraft or satellite platform. Atmospheric constituents such as gas molecules, small particles called *aerosols*, larger particles called *particulates*, and water in liquid and solid form (e.g., cloud droplets, raindrops, and ice) have the ability to absorb (intercept) and/or scatter (redirect) EMR. Of these interactions, scattering is the most important factor for solar reflected radiation, while absorption is more important when sensing long-wave emitted radiation. Atmospheric scattering diffuses the direct solar irradiance, reduces the amount of reflected solar radiation traveling to a sensor, and redirects solar radiation into the view of the sensor. Absorption limits which wavebands within the EMR spectrum are useful for sensing Earth's surface properties. For long-wave (TIR and microwave) sensing, absorption reduces the magnitude of emitted radiation leaving a surface and results in the atmosphere reradiating EMR into the view of a sensor.

The spectral signature of a surface material or object is the characteristic pattern of the magnitude of reflected or emitted EMR as a function of wavelength. As a type of inversion problem, information about the composition or condition of surface features can be extracted from spectral signatures represented in remotely sensed data. The amount of reflected EMR captured by a remote sensor is primarily a function of the reflectance properties of the surface materials. However, the reflected EMR leaving a surface is also

influenced by the magnitude and direction of the solar irradiance and the view direction of the remote sensing instrument. The amount of emitted long-wave radiation leaving a surface is primarily a function of the surface temperature and, to a lesser extent, the emissivity of the surface. Radar sensing is achieved by a process in which microwave EMR is actively transmitted from an antenna and the backscattered EMR is received by the antenna, which is operated in a side-looking mode. The amount of backscatter, and therefore the strength of the received signal, is primarily a function of the moisture, microroughness, and geometric characteristics of surface materials and features.

Types and Sources of Remotely Sensed Imagery

Numerous types and sources of remotely sensed image data are available. The selection of the most appropriate image type should be based on a close match between the spatial, temporal, and attribute aspects of one's information requirements and the spatial, spectral, radiometric, and temporal characteristics of the available imagery. Two important specifications associated with these characteristics pertain to two data properties: (1) resolution or grain and (2) extent or coverage. Spatial resolution and extent aspects of an image characterize the fineness of spatial detail and the areal extent covered by an image, respectively. Each spatial characteristic must be traded off relative to the other; that is, high spatial resolution comes at the expense of limited coverage, and vice versa. Spectral resolution pertains to the range of wavelengths for a particular spectral waveband, while the number and location of wavelength bands in the EMR spectrum determine the spectral coverage. Radiometric resolution and coverage pertain to the fineness and range of EMR energy levels quantified by a remote sensor. The finer the radiometric resolution, the greater the ability to quantify fine differences in surface properties or identify subtle differences in surface material composition. Finally, temporal resolution and duration, which are mostly determined by aircraft or satellite mobility characteristics, represent the time interval between remote sensing observations and the record length of available data, respectively.

The primary differences between imagery types are associated with the type of (1) platform (airborne vs. satellite) and (2) sensor (photographic vs. digital and optical vs. microwave). Airborne imagery is captured by sensors on fixed-wing (e.g., airplanes and jets) and rotary-winged (e.g., helicopters), or lighter-than-air (e.g., blimps) platforms. Airborne platforms operate at lower altitudes and tend to be more flexible and mobile than satellites. They are able to provide imagery with higher spatial and temporal resolution but usually with more limited spatial and temporal coverage. Satellites normally provide regular, large-area image coverage at set times and with coarser spatial resolution. The two principal types of satellite orbits, sun synchronous (i.e., polar orbiting) and geostationary (i.e., equatorial orbiting), determine spatial and temporal resolution and coverage characteristics. Sun-synchronous satellite systems are able to provide higher-spatial-resolution images less frequently, while geostationary systems provide frequent images that cover much of the globe simultaneously but with coarser spatial resolution. Photographic cameras capture imagery on film, providing very high spatial resolution and fidelity but limited flexibility in spectral range and image formats. Higher spectral and radiometric qualities are achieved with digital sensors such as digital camera systems and optical-mechanical scanners, which directly measure EMR levels in an electronic, computer-compatible manner. Aerial photographic film can be electronically scanned to produce digital images. Digital images are more readily corrected, enhanced, and converted into geographic information system (GIS)-compatible form. Digital image data can be transferred by electronic means through microwave downlink and wired communications.

Particular platform-sensor combinations tend to be used to capture the most commonly available imagery, though any type of imaging sensor can operate on either airborne or satellite platforms. The most common airborne imagery has been aerial photography. The use of airborne digital cameras and linear array sensors to capture high-spatial-resolution images of land areas is increasing rapidly. Aerial photographic film is available in black-and-white panchromatic, black-and-white infrared, true-color infrared

(CIR), and false-color infrared formats. Most satellite imagery is captured by digital imaging radiometers, since it is difficult to retrieve photographic film from a satellite. These sensors capture images through *pushbroom* sampling, using a large linear array of detectors, or *whiskbroom* sampling, using oscillating mirrors and a few detectors.

The three primary means for acquiring image data are as follows:

1. Obtaining existing imagery from an archive source
2. Capturing one's own imagery
3. Hiring a commercial firm or public agency to acquire new imagery coverage

Obtaining existing imagery is the least expensive, since the cost of acquisition has been subsidized. However, with this approach, one has no control over the spatial, spectral, radiometric, and temporal characteristics of the imagery. Of course, this is the only means for acquiring historical imagery. If current imagery is needed or no source of useful imagery exists, one can capture one's own airborne imagery. Consumer-level digital cameras and video sensors enable convenient imaging from a rented aircraft. To capture vertical imagery, one may need to design, build, and install a camera mount. Though not suitable for precise mapping, such imagery can be useful for reconnaissance and qualitative landscape assessments, particularly along linear features such as streams, roads, or utility corridors and for inventorying (i.e., making counts of) surface features.

If current imagery is needed and/or particular spatial or spectral image characteristics are required, then imagery must be purchased from a commercial vendor. Aerial survey firms can provide new and archived aerial photography and/or digital airborne imagery. Similarly, satellite

imagery with high (starting in 2000) and moderate (since 1972) spatial resolution can be obtained from both public and commercial suppliers around the world.

Interpreting Remotely Sensed Images

Image interpretation is the act of analyzing remotely sensed images and extracting useful information about a scene, the Earth surface area represented by an image. Interpreting images is

both an art form and a science. Humans have innate interpretative abilities, but interpretative ability improves with experience. By following scientific principles of systematic investigation and establishing interpretative rules, information extraction can be optimized and subjectivity can be minimized.

There are four general types of image interpretative tasks that an image analyst may wish to accomplish. In order of complexity, these tasks are as follows:

1. **Detection:** Locating the occurrence of a particular type of feature or phenomenon; a binary or dichotomous search process (e.g., detecting standing water or the presence of vegetation)
2. **Identification:** Locating or delineating and determining the types of features or phenomena (e.g., identifying vegetation community types)
3. **Measurement:** Quantifying the length, area, or number of occurrences of objects (e.g., measuring the length of a road segment or counting the number of dwellings in a neighborhood), once such objects have been detected or identified
4. **Analysis:** Examining the spatial relationships and geographic attributes of a scene (i.e., the ground area covered by an image), often by incorporating information derived from detection, identification, and measurement of scene objects and phenomena (e.g., analyzing the socioeconomic characteristics of a neighborhood or inferring habitat quality from vegetation patterns)

These general image interpretation tasks are performed for a variety of geographic applications, including

1. renewable resource management;
2. exploration and engineering geology;
3. urban and transportation planning and engineering;

4. emergency response, law enforcement, and military reconnaissance; and
5. scientific explorations.

Appropriate tools and strategies for image interpretation vary depending on whether images are in hardcopy or digital form. Most hardcopy images are aerial photographs, which are not normally geographically referenced. As for a map, the spatial scale of a hardcopy image is specified by the representative fraction, the ratio of the length of a feature on an image to its actual length on the ground. The representative fraction should be expressed as a dimensionless ratio per unit image length (e.g., 1:10,000 scale or 1/10,000 scale). However, it is common practice for local government agencies in the United States to use dimensioned-scale equations in nonmetric units (e.g., 1 in. [inch] = 2,000 ft. [feet]). Dimensioned-scale equations can be readily converted to a dimensionless representative fraction by converting the units of one side of the equation to match the units of the other side (e.g., 1 in. = 2,000 ft. → 1:2,000 scale; 1 in. = 24,000 ft. → 1:24,000 scale). Since the representative fraction increases when the denominator (called the *scale factor*) decreases, a large-scale image portrays a smaller areal extent with greater spatial resolution than a small-scale image. The scale of uncorrected aerial photographs captured over varying terrain varies across the image, making it difficult to measure lengths and areas in an accurate manner.

Hardcopy images can be interpreted with the aid of analog optical viewing tools such as magnifying film loops or microscopes. Aerial photographs are often captured with approximately 60% overlap to enable stereoscopic viewing. A *stereoscope* is a device that forces each eye of the interpreter to simultaneously view each overlapping portion of the photographic pair, such that the interpreter observes the scene in three dimensions. Being able to see topographic features and terrain variations in stereo is very effective in visualizing landscape relationships or mapping terrain-controlled features such as vegetation. If a digital GIS layer is to be generated from an analog map, the map must be digitally encoded by scanning or manually digitizing the interpreted features.

Digital images can be displayed and viewed on a computer monitor or printed onto a variety of hardcopy media. Computer-based image processing and display systems enable interactive viewing, processing, and interpretation in a very flexible and efficient manner known as *on-screen interpretation*. While a novice image analyst may not attempt to exploit the semiautomatic image interpretation (e.g., image classification or object recognition) and quantification capabilities of image-processing software, on-screen interpretation is readily achievable and powerful. The purpose of more automated approaches is to generate and update geospatial data sets in a faster, cheaper, more repeatable, and more reliable manner. Though the reliability of semiautomated approaches is improving, some form of manual, interactive editing and quality checking of the resultant products is required.

Up to three different wavelength bands, enhanced images or dates of imagery can be displayed simultaneously in the three color planes (red, green, and blue) of a computer image display. A single-band, panchromatic (i.e., broad visible wavelength band) satellite image can be displayed simultaneously in all three color planes to yield a gray-tone (i.e., black and white) image. True-color images are displayed when red-, green-, and blue-wavelength bands are displayed in red, green, and blue color planes, respectively. When other waveband/color plane combinations are displayed, the resultant images are called *false-color composites*. The most common is the false-color infrared composite, where near-infrared, red, and green wavelengths are displayed in red, green, and blue color planes, respectively. As with the color representation of CIR photographs, healthy green vegetation appears bright red, and inorganic urban surfaces (e.g., concrete and roofing materials) are portrayed in blue-gray.

Many image analysis and mapping tasks can be performed with digital images displayed on a computer monitor. An analyst can conveniently modify the scale and tone/color of a digital image and, using image-processing software, correct and enhance spatial and radiometric characteristics. (Image corrections and enhancements can also be performed by image suppliers prior to obtaining the imagery.) Spatial scale may be changed by digitally zooming, which means that there is no

inherent representative fraction associated with an image displayed on a computer monitor. Once an image is enhanced and displayed, an analyst can visually interpret the image on the computer monitor. Point, line, and polygon objects can be counted, measured, and/or digitized interactively by cursor control devices (e.g., mouse). Information attributes (e.g., category names) about these spatial objects must be encoded manually. These encoded objects can be saved to a digital file. If the image has been georeferenced, then a file of image-digitized features with encoded attributes is essentially a GIS layer. Similarly, a dated GIS file can be overlaid graphically with a more current georeferenced image and be updated interactively through this “heads-up digitizing” approach.

Conclusion

Remote sensing provides an efficient means for deriving geospatial data and information about Earth's surface (and atmosphere). Many geospatial data and information requirements can be met through visual interpretation of remotely sensed images. Digital imagery and image-processing software are becoming more accessible, allowing for more efficient and reliable interpretation and digital encoding of geospatial data.

Remote sensing is a rapidly advancing technology and the availability, cost, and characteristics of remotely sensed imagery change constantly. Most of these changes are positive, meaning that the imagery is becoming higher quality and is available in a more convenient, timely, and economical format.

REMOTE SENSING: PLATFORMS AND SENSORS

Remote sensing in geography is recognized as the technology of acquiring geographically referable information on the land, ocean, and atmosphere without having physical contact with the object under study. A wide range of sensors for acquiring the data about Earth and its environment are in use in remote sensing. Sensors are required to be fixed in a stable platform for recording, storing, and transmitting the data into ground-based receiving stations.

Platforms

In remote sensing, the vehicle or structure that carried a sensor is called a *platform* (Table 1; Figure 1). Airborne or space-borne platforms are often used in remote sensing of the environment. Aircraft or balloons are some examples of airborne platforms, while satellites or space shuttles can be considered as space-borne. Balloons, considered to be the cheapest airborne platforms, are often used for academic training, experiments, and rapid damage assessment purposes. However, ground-based platforms are also in use. Towers, scaffoldings, and cars can be used as ground-based platforms to record detailed information about the surface for experiments to validate data collected from other sources.

Platform	Altitude	Remarks
Geostationary satellite	36,000 km	GMS, NOAA-GEOS, DMSP, INSAT, etc.
Circular orbit satellite	500~1,000 km	IRS-1C, LANDSAT, ALOS, Quickbird, etc.
Space shuttle	240~350 km	SRTM project
High-altitude jet plane	10~12 km	Reconnaissance, aerial surveys, etc.
Low-altitude plane	500~8,000 m	Aerial surveys
Helicopter	100~2,000 m	Aerial surveys
Radio-controlled plane	~500 m	Airplane, helicopter
Hang-plane	50~500 m	Hang-glider, paraglider, etc.
Hang-balloon	~800 m	Hydrogen balloon
Ground based	0~200 m	Tower, crane, car, cherry pickers, etc.

Table 1 Types of platforms

Aircraft are commonly used platforms to collect detailed images and facilitate the collection of data about Earth's surface at desired times. Cameras mounted on aircraft have been used to monitor land use practices, locate forest fires, and produce detailed and accurate maps of Earth's surface based on aerial photographs captured with aircraft-mounted cameras. Remote sensing can be also conducted using space shuttles. The NASA Shuttle Radar Topographic Mission (SRTM) 90-m Digital Elevation Data for the entire world was one of the examples of using a space-borne platform, namely, the space shuttle. However, with the advancement of technology, satellites are becoming commonly used space-borne platforms in remote sensing.

Satellites are placed outside the atmosphere at a large distance, orbiting around the Earth at a designated time frequency. Because of their flight path, satellites permit repetitive coverage of Earth's surface on a continuing basis. The Landsat, SPOT, RADARSAT, IKONOS, ALOS, and NOAA satellites are some examples of satellites that have been providing data about the Earth at various scales for more than four decades. The data acquired by each platform may possess specific data characteristics within the constraints imposed by the individual sensors.

Some satellite platforms are *sun-synchronous*, while some are *geosynchronous*. A sun-synchronous satellite passes over the same part of Earth at roughly the same local time each day. RADARSAT, Landsat, SPOT, and COSMOS are examples of sun-synchronous satellites. A geosynchronous satellite has an orbital track around Earth that it repeats regularly over time. For example, if a satellite's orbit lies over the equator and the orbit is circular, it is called a *geostationary* satellite. Geostationary meteorological satellites and NOAA satellites are examples of geosynchronous satellites.

Sensors

Remote sensing devices are called *sensors*. Sensors are designed to record *electromagnetic radiation* (EMR). EMR is energy transmitted through space in the form of electric and magnetic waves. Sensors record specific wavelengths of the electromagnetic spectrum (a range of electromagnetic

Figure 2 A general schematic diagram of sensor types

radiation extending from cosmic waves to radio waves) in various bands (most importantly in the visible, infrared, and microwave bands) to use the benefits of the absorption or transmission properties of Earth and the atmosphere.

Sensors may be fixed on space-borne, airborne, and terrestrial platforms to acquire geophysical data from global to local scales. A platform may carry several sensors. For example, Landsat ETM, a space-borne platform, has multiple sensors that record electromagnetic energy reflected from Earth's surface in different bands ranging from visible to infrared and thermal bands at various spectral resolutions. Application of data generated from the remote sensing techniques depends on sensor resolution capabilities. Some of the sensors mounted on an airborne platform, especially in aerial photography, are capable of data acquisition at the 0.08-m (meter) level, while

some sensors fixed in space-borne platforms such as Quickbird provide data up to 0.6 m of spatial resolution.

Sensors are most often classified into two categories: passive and active (Figure 2). *Passive sensors* detect the reflected or emitted electromagnetic radiation from natural sources. Sunlight is the most common natural source of radiation measured by the passive sensors. Those sensors that use lenses in the visible and reflective infrared region are often called *optical* sensors. The wavelength region usually extends from the visible and near-infrared (VNIR) to shortwave infrared (SWIR). Aerial survey cameras, space cameras, radiometers, fourier spectrometers, and multi-spectral scanners are some of the examples of passive sensors.

In general, remote sensing sensors include panchromatic, multispectral, and hyperspectral

sensors. *Panchromatic* sensors record information in a wide range of wavelengths, including the visible and near-infrared spectrums, into one band, while *multispectral* sensors cover two or more spectral bands, recording the bands simultaneously. *Multispectral scanners* (MSS), widely known sensors used in the early Landsat series, record radiation in multiple-wavelength regions of the visible, near-infrared, middle-infrared, and thermal-infrared parts of the electromagnetic spectrum. *Hyperspectral sensors* cover spectral bands narrower than multispectral sensors and record the image data from several hundred bands at the same time, offering greater spectral resolution than the multispectral sensors. The airborne visible/infrared imaging spectrometer (AVIRIS), an example of a hyperspectral remote sensing sensor, delivers calibrated images in 224 contiguous bands. The passive sensors are unable to penetrate the clouds over the target, and the quality of data mostly depends on daytime sunlight. Since the information spectrums recorded by passive sensors are strongly affected by atmospheric scattering, the usefulness of these devices may be limited by atmospheric conditions. MODIS, ASTER, IRS-1C, and SPOT satellites are some of the platforms that have carried passive sensors.

Active sensors detect reflected responses from objects that are irradiated from artificially generated energy sources. The platforms that have active sensors carry their own flashlight-emitting microwaves to illuminate their targets. In this case, the image of the object surface is formed by measuring the microwave energy scattered by the ground or sea back to the sensors. Because the artificial energy source system, especially on satellite platforms, requires large solar collectors and storage batteries, it may not operate continuously; some satellites are limited to 10 minutes of operation per hour.

RADAR can be considered as an example of an active remote sensing sensor, where the time delay between emission and return is calculated to locate the geographical position and height of stationary objects and also the directionality of moving objects. Furthermore, the antenna is a key element of a radar sensor. For a given position in space, the resolution of the remotely sensed image is a function of the antenna size, in what is called *real-aperture radar*, or RAR. The

data collected by the RAR is limited by the antenna size regardless of sensor path. Therefore, the synthetic aperture radar (SAR) system was developed to remove the antenna constraint by synthetically propagating the antenna. Laser spectrometers, laser altimeters, and microwave radiometers are a few other examples of active sensors. The advantage of an active sensor over a passive sensor is the capability of the former to record information about the environment regardless of night and cloud cover. An ALOS platform consists of both passive (AVNIR-2) and active (PALSAR) sensors, while RADARSAT carried only an active sensor.

Future Directions

Currently, many innovative research projects directed at the development of platforms and sensors are in progress, with the overarching goal of ushering in a wider availability of remotely sensed data, reducing the data cost, and enabling a widespread analysis of environmental change. Low-cost space-borne platforms such as microsatellites are being developed to collect data over a geographic location for a specific application or purpose. Small, unmanned, radio-controlled aerial-survey aircrafts are also being developed for a faster response to natural disasters such as wildfires. Other efforts promise to provide higher spatial, temporal, and radiometric resolutions in the days to come. For example, further improvement of hyperspectral remote sensing will include ultraspectral frequencies that may result in thousands of imaging bands providing the data at a fraction of today's wavelengths. It is expected that the next generation of remote sensing sensors will be able to provide data at higher spectral and spatial resolutions to expand our understanding of geological processes and mineralogy, climate change, health, and human-induced processes. However, the increasing volume of data coming from hyperspectral and hyperspatial sensors will challenge data mining, processing, backup, and retrieval capabilities.

REMOTE SENSING IN DISASTER RESPONSE

Remote sensing is the observation of phenomena at a distance, using a range of sensors for object identification based on their spectral signature, that is, the degree to which they absorb, reflect, backscatter, or emit light at various segments of the electromagnetic spectrum. Remote sensing can be accomplished from aircraft, from Earth-observing satellites, and from specialized in situ devices. Remote sensing technology has been used to facilitate first-responders' decision support for a wide array of biogenic (naturally caused) and anthropogenic (man-made) disasters. Such natural disasters include landslides, snow disasters, volcanic eruptions, floods, hurricanes, earthquakes, tsunamis, droughts, famines, epidemics, and epizootics. Anthropogenic disaster responses that have benefited from remote sensing data include both inadvertent disasters (e.g., pollution, mining accidents, hazardous chemical and oil spills, train derailments) and deliberately caused disasters (e.g., acts of terror, arson-related fires).

Aircraft have the advantage of capturing high-resolution panchromatic, multispectral and hyperspectral data from low-altitude flights, thereby providing high spatial and high spectral resolution, with a minimum of atmospheric distortion; but due to the infrequency of airborne sensor flights, they

lack the high temporal resolution offered by satellite remote sensing. Geostationary satellites, whose orbits are in sync with Earth's rotation, capture data 24 hours per day, 7 days a week, while polar-orbiting satellites, depending on their revisit time, may collect data over the same area several times per day. Current analytical software for image analysis can minimize the impact of atmospheric distortion for both multispectral and hyperspectral orbiting sensors. Moreover, satellites with radar sensors can penetrate cloud cover.

In situ devices, ranging in sophistication from simple rain gauges to seismometers to NEXRAD Doppler Radar installations, monitor variables such as local precipitation, temperature, humidity, barometric pressure, water levels and quality, soil moisture, seismic activity, biological and chemical pollutants, and so on. Such in situ data can be used to supplement both aircraft-borne and space-borne sensor data. For disaster management purposes, other sources of data are also crucial, including demographic data, socioeconomic data, structural data, transportation network data, epidemiological data, and so on. Advanced technologies for in situ remote sensing are exemplified by micro unmanned aerial vehicles (MUAV), which can be deployed with sensors to detect explosives, toxic liquids or gases, radiation, biological or chemical weaponry, as well as hazardous industrial effluent.

The mechanism for integration of such diverse sources of information is typically a spatial database or geographic information system (GIS), which allows for multiple data layers and the means to analyze them in specific combinations. Online shared GIS allows end users to serve as sentinels during major disasters and participate in damage assessment. The other space-based technology that plays a vital role in disaster response is the constellation of geopositioning satellites, which can give exact location (i.e., latitude/longitude or Universal Transverse Mercator (UTM) information). There are now four such geopositioning constellations, the United States' Global Positioning System (GPS), the European Union's Galileo, Russia's GLONASS, and China's Beidou (Compass).

The International Charter—Space & Major Disasters (www.disasterscharter.org) is a consortium of satellite-owning governments and companies that freely distributes satellite data through authorized users to areas that have experienced a

declared disaster. Such data are used for evacuation support, search and rescue, determining the extent of damage, facilitating access to medical and humanitarian shelter facilities, and so on. Since its first activation in February 2002, as of July 10, 2009, the charter has been activated 198 times, providing free satellite data to countries worldwide for virtually every known catastrophic event. Charter members and their space-based resources include the U.S. Geological Survey's Landsat, the National Oceanic and Atmospheric Administration's (NOAA) POES and GOES, Canada's RADARSAT, France's SPOT, Argentina's SAC-C, the European Space Agency's ENVISAT and ERS, India's IRS, Germany's Terra SAR, China's FY, SJ, and ZY satellites, Japan's ALOS, and, from the private sector, GeoEye-1, Digital Globe's Quickbird, and Qinetiq's TopSat. The charter also includes the Disaster Monitoring Constellation (DMC). On July 29, 2009, a Russian Dnepr Rocket launched two satellites, Spain's Deimos-1 and the United Kingdom's DMC-2, that are part of the multicountry DMC, which include Algeria's AISAT-1, Turkey's BilSAT (decommissioned in 2006), Nigeria's SAT-1, the United Kingdom's DMC, and China's Beijing-1.

Other international agencies and initiatives directly involved in disaster response include the United Nations Disaster Relief Organization (UNDRO) and the recently created UN SPIDER (Space-Based Information for Disaster Management and Emergency Response), a division of the United Nations Office for Outer Space Affairs (UNOOSA), which is specifically chartered to develop optimal applications of space-based technologies for societal benefit. The North Atlantic Treaty Organization (NATO) has also funded development of the Kamal Ewida Earth Observatory: real-time remote sensing ground stations at two universities in Cairo, Egypt, in collaboration with universities in Turkey and the United States, to support early warning and mitigation of disasters, including epidemics. This initiative was preceded by the World Summit on the Information Society (WSIS) Summit II, held in Tunis in 2005, addressing the remote sensing role with respect to natural disasters, as well as by the (ongoing) agenda of the African Association of Remote Sensing of the Environment (AARSE)

There is an increasing awareness that remote sensing's utility goes far beyond disaster response,

in that the technology has a role to play in decision support at every stage of the entire disaster management life cycle: vulnerability assessment, disaster preparedness, early warning, disaster mitigation, emergency response, humanitarian relief, damage assessment, postdisaster reconstruction planning, refugee resettlement, and societal rehabilitation. There has also been a steady evolution in the sophistication of modeling techniques that integrate remotely sensed data, specifically for disasters. The U.S. Federal Emergency Management Agency's (FEMA) HAZUS-MH for flood events, hurricanes, and earthquakes; the U.S. Coast Guard's CAMEO for oil and chemical spills; the U.S. Army Corps of Engineers's HEC-RAS for flooding; and IBM's public domain Spatiotemporal Epidemiological Modeler (STEM) for disease outbreaks are all examples of models for multiple hazards, which use satellite data as input.

Current trends in disaster management include recognition that while some disasters are more imminent than others, the potential intensity of certain longer-term disastrous events is such that they also demand immediate attention. These include the global and regional impacts of climate change, which could exacerbate drought and desertification in the African Sahel, thereby affecting food security and potable water availability, as well as the acceleration of polar ice melting, thereby raising sea levels, which would threaten island nations and coastal communities. Global warming is also associated with increasing the breeding season for the insects that serve as vectors for infectious diseases. Remote sensing has accordingly been applied to identifying and monitoring vector habitat and mapping disease prevalence in order to mitigate epidemics among human populations and epizootics among animal populations.

In an attempt to intensify research on disaster mitigation and to train the next generation of scientists dedicated to improving disaster management methodologies, several government laboratories and universities worldwide have established real-time remote sensing ground stations. These facilities use high-performance computing resources to develop spatial data products in near-real time to support early warning and mitigation of disasters and an effective response to time-critical disaster events, as well as geospatial

analysis methodologies to intelligently merge heterogeneous data sources.

The populations at greatest risk of being negatively affected by a wide range of disasters are those living in poverty. As a consequence of their impoverishment, they live in areas more prone to natural disasters, lack the means to easily evacuate even when early warning is given, do not have the resources to rebound readily after a disaster, and are more likely to suffer from the synergistic relationship between malnutrition and infection. Although remote sensing has been of help in poverty mapping and in supporting decision makers' disaster response, it will require political will on the part of the highly industrialized countries to confront poverty as the principal underlying factor in disaster vulnerability, whether among the low-income communities in Africa, Asia, and Latin America or in the United States, as Hurricanes Katrina and Rita dramatically demonstrated.

RENEWABLE RESOURCES

Renewable resources are commonly understood to be the environmental components—wind, sunlight, water, forests, crops, fisheries, and so on—of complex socio-ecological systems that, if managed properly, can meet human needs for raw materials, energy, and food on a long-term, sustainable basis. Societal interest in renewable resources stems from increased awareness of the problems resulting from reliance on nonrenewable resources (fossil fuels and minerals). Overdependence on these resources contributes greatly to air and water pollution, global climate change, geopolitical conflict, resource wars, economic instability, and other major difficulties that many believe can be addressed only by a global transition to economies that are based on renewable resources. Practically and conceptually, such a transition requires an appreciation of the complex socio-environmental character of resources and renewability. This entry considers this character and explores how issues of scale, uneven resource distribution, and political power influence the potential for renewable resource systems to emerge.

Resources do not simply exist, they *become*, observed geographer Erich Zimmerman in 1939. They do so through the coevolution of ecological systems and human societies, and their degree of “renewability” depends on how one bounds the analysis. To explore this way of looking at resources, take the case of solar energy, a potentially highly renewable resource. The sun provides Earth enough solar radiation to power the planet’s climate and life support systems and is expected to continue doing so free of charge, maintenance, or pollution for another 5 billion years in quantities far exceeding human demand. The “waste” associated with these solar flows is heat that warms the planet before radiating harmlessly into space. Solar energy is thus highly renewable and sustainable from both an energy supply and an ecological standpoint.

Solar energy becomes a human resource, however, through socio-environmental technologies that capture and convert its potential energy into commodities and services. Plants, for example, are “natural” devices for solar capture and circulation (e.g., as food or biofuels), but they constitute renewable resources only to the extent that people help maintain the conditions under which the desired plant species can thrive and be harvested repeatedly despite human and ecological perturbations. Fisheries, forests, and soils are likewise viable renewable resources when managed through social institutions that prevent their being overwhelmed by pollution, petrochemicals, overharvesting, habitat loss, or competition from less desired species.

Other solar harvesting devices appear more “technical” in nature. Windows, for example, may seem to be relatively simple and ubiquitous manufactured products that allow people to use sunshine to light and heat buildings. They are only possible, however, in “collaboration” with nature, which provides the raw materials, energy, and the rules by which the combination of these inputs will produce glass. Even less visible are the political, scientific, and entrepreneurial dimensions of windows; these are perhaps best revealed through the effort by sustainable energy advocates in recent decades to get states to mandate the use of higher-performance windows in buildings. The effort has spurred technical innovation in, marketing of, and ultimately the installation of windows that can better manage flows of sunlight and heat into and out of buildings—to, in effect, allow solar energy

The Mammoth Pacific geothermal plant, located in the eastern Sierra Nevada mountain range in California, showcases the environmentally friendly nature of geothermal power. Three air-cooled binary units generate a total of 28 megawatts of electricity and release essentially no emissions into the atmosphere or land surface. Geothermal power plants such as Mammoth use many of the same components used by traditional power-generating plants. However, the geothermal resource is relatively cool, and the wells can produce fluids, steam, or brine.

to *become* a more powerful and renewable resource.

Similarly, to reduce climate change while also extending electricity service to the 1.5 billion people who presently lack access, significant effort has gone into creating the conditions for rapidly expanding the market share of solar, wind, geothermal heat, and other renewable resources beyond their 2% current contribution to global electricity generation. The critical issues for expanded development turn not on the adequacy of the renewable resource base, which is vast, but instead on how energy markets are designed and how inventors, entrepreneurs, financiers, and others perceive the risks and rewards of renewable resource investments. Historically, market rules and government policies have strongly favored developers of nonrenewable fossil fuel

resources, whose economic and hence political power has stemmed from the ability to control and exploit, through economies of scale, the geographically uneven distribution of these fuels. It is only recently, through sustained advocacy and a renewed sense of crisis in the West concerning oil and coal dependence, that investment in wind and solar power has exploded, bringing down costs and increasing capacity at unprecedented rates.

The extent to which such investments effectively promote renewable resource development involves issues of scale and “whole-systems” analysis. Corn-based ethanol fuel production, for example, looks far less renewable when its large fossil fuel inputs and adverse food system impacts are considered. Similarly, small run-of-river microturbines working within intact riparian ecosystems are qualitatively

different from massive hydropower dams that are among humanity's largest and most ecologically (and often socially) disruptive projects. A fundamental challenge to meeting human energy and materials needs through renewable resources is the constantly expanding demand for goods and services driven by increasing population and the continual pursuit of "economic growth" in most capitalist and noncapitalist societies. What may be renewable on a small scale often is not on a larger scale.

To date, industrial(izing) societies have generally sought to meet their economic growth imperative by substituting nonrenewable, depletable resources for renewable resources—living off nature's "capital" rather than its "income." As information technologists and other high-tech entrepreneurs have become interested in bringing concepts of mass production, short innovation cycles, and fast product development to the energy sector, there is a growing potential for breakthroughs in renewables, especially because historically the sector has directed most of its meager research and development effort into massive, conventional energy facilities.

The dynamic, socio-environmental conception of renewable resources presented here seeks to highlight not only the environmental attributes and adequacies of various resources but also the social and technical dimensions that help or hinder their development.

RENT-GAP

One of the more popular explanations for gentrification, the rent-gap hypothesis, first advocated by Neil Smith, approaches this issue in terms of the profitability of land in the urban core. In centrally located sites, actualized ground rents generally decline over time as the buildings and infrastructure age. During the post-World War II boom, low rents on the urban periphery were a major attraction to capital. Deindustrialization and the flight of people and capital to suburbia throughout the late 20th century played a major role in lowering the profitability of land, or devalorizing it, in the central business district (CBD). Low-income residents were incapable of generating rents that guaranteed a high rate of profit. Disinvestment from the urban core was manifested in abandoned buildings and lack of repairs.

However, in contrast to actualized rents, the *potential* rents in such locales remained high. As neoclassical economists tend to frame the issue, urban land was not being put to its so-called "highest and best use," that is, generating the maximum possible rate of profit. In particular, the rapid growth of producer services over the past three decades and their reliance on agglomeration economies elevated the importance of locations in maximally accessible places. Thus, a significant discrepancy arose between potential and actual rents, in other words, a rent-gap. Real estate developers and others with a vested interest in land sensed that higher rates of profit (rental streams) may be earned by attracting corporate capital or higher-income residents. Lured by the potential profitability of these sites, capital, much of it speculative, began to flow into urban cores in vast quantities as corporations reclaimed the spaces of inner cities, stimulating a building boom in luxury residential uses and commercial ones such as offices, waterfront developments, and sports stadia. The emergence of such land uses is usually accompanied by an influx of well-paid professional labor. Typically, such a process involved the invasion and displacement of low-income, working-class, often ethnic minority communities. The rent-gap thus closed, at least temporarily, until future fluctuations in the economy threaten to re-create it.

The rent-gap thesis ties waves of building construction in the landscape to the dynamics of capital accumulation, investment, and uneven development. It offers a structuralist, production-oriented explanation of gentrification that does not rely on demographics or the residential preferences of yuppies. Thus, it posits gentrification in terms of the structural dynamics of class, labor, and capital rather than individual preferences or lifestyles. Critics have alleged that the thesis is economic and functionalist, leaving little room for human agency.

REPRESENTATIONS OF SPACE

Broadly, representations of space encompass all the ways in which humans bring geography into consciousness, including symbols, maps, remote sensing, models, art and photography, and textual descriptions. More specifically, however, the term *representations of space* comes from the French philosopher Henri Lefebvre's famous work, *The Production of Space* (1991). This entry provides an overview of Lefebvre's theory, describes some of the factors that create new representations of space, and examines the manifestation of representations of space in physical space. It then reviews some of the representations of space that have been produced by geographers, such as cartography, and discusses the impact of the quantitative revolution and the cultural turn on the representations of space created by geographers.

Lefebvre's Theory of Space

For Lefebvre, a neo-Marxist, representations of space, along with spatial practice and representational space, formed the conceptual triad through which he analyzed the social production of space. Lefebvre's goal in using this triad was to introduce a unifying theory of space that he hoped would encompass physical space, mental or metaphoric space, and social space under one theory that could de-fetishize space, revealing the social relations and modes of production that are embedded within it. Lefebvre argued that historically specific spaces embody the modes of production and social relations that help them come into being and, at the same time, are necessary for those social relations to exist. However, space had become so fragmented by philosophy and other disciplines that these social relations had become incoherent in existing analyses. As both determinant of social relations and determined by them, space is presented as a crucial factor in understanding society. Whenever society changes in a revolutionary way, a corresponding new space must also be created. However, like a palimpsest, these new spaces do not erase older ones completely.

A second part of the triad includes spatial practice, sometimes referred to by both Lefebvre and others as *perceived space*, which is the daily spatial reality of a society, the domain of production and social reproduction. Representations of space, or conceived spaces, are associated with the codification of space and how social relations are inscribed on space. Representations of space fall under the control of "experts," who map and define what is possible in any given space. Thus, representations of space reflect the dominant ideology of a given society.

Finally, representational spaces, or lived spaces, are associated with the imagination, with symbols, and with clandestine meanings. This is the space of art and dreams and is often made unrecognizable by representations of space. This is also the space from which challenges to hegemonic ideologies are launched, the space of possibility and contingency.

Lefebvre noted that all representations of space are, by necessity, reductions. It is impossible to represent or describe all things that occur within a particular space. For any given society or mode of production, it is the hegemonic discourse

within that society that dictates what aspects or objects are removed or reduced in a representation of space. Therefore, most representations of space work in favor of power. Furthermore, these representations are always presented as scientific and produced by experts, and they are presumed to be received uncritically. For this reason, Lefebvre argues that representations of space, taken alone, serve only to confuse and obfuscate analyses of space. Challenges to hegemonic social relations are not found in representations of space but rather are forced underground into the realm of representational spaces.

Impact of Shifts in Social Relations

As noted above, major shifts in modes of production or social relations could not occur or be expected to endure without the creation of new spaces and representations of space. One such example, drawn from the work of Denis Cosgrove, is the creation of geographical perspective in landscape art in 13th-century Tuscany. This new representation of space came into existence just as the Tuscan economy began to shift toward an accumulationist regime in which vast amounts of wealth were produced through trade and the emergence of a new urban class of craftsmen. This new representation of space has been likened to a new way of seeing, one that was intimately associated with questions of ownership, power, and the new regime of wealth accumulation. The perspective of the paintings was that of a single, controlling eye, with mastery over what it surveyed. Those who worked on the land or produced the landscape were removed from the scene, their toil elided. Their removal served two functions: First, it gave the illusion of total control to the viewer, often the owner of the land and the person who had commissioned the painting; second, the landscape produced a false ideal of nature, expertly manicured and crafted and devoid of conflict or tension.

Effects of Representations of Space on Physical Space

Representations of space, being the realm of experts and the reflectors of ideology, can and have had a profound effect on physical space. Lefebvre argued that ideology, in fact, can only

endure if it takes on a spatial body. Using Christianity as his example, he argued that it would not have endured as a cultural practice if it had not created spaces—churches, confessionals, cathedrals, and so on—that gave physical space, a body, to its message. In similar ways, all sorts of representations of space are made into physical spatial reality. An architect's plans, once constructed, stand as a physical manifestation of the representation of space. In the realm of cartography, the U.S. Public Land Survey System existed first as a series of maps dictating ranges and townships around meridians and base lines and then was made manifest on the landscape in the form of country roads, fields, and town plots.

It should by now be clear that geographers have always been and continue to be in the business of producing representations of space. However, the methods they have used to do so, and the ideologies that have been written into the representations of space that have been produced, have varied over the long course of the history of geography as a discipline.

Cartography

Perhaps the most obvious representation of space produced by geographers has been the map. Until very recently, little thought was given to the ways in which ideology and discourse are included not just in the production of the map itself but in the very act of mapping. Because cartography is treated as a science, and maps are supposedly judged on their "accuracy" in presenting real-world phenomena, little thought has been given to the purposes for which maps have historically been produced.

Practically from the moment of its creation, cartography has been associated with conquest and empire. From the Ottomans to the Moguls to the Romans and Egyptians, early leaders all employed or patronized cartographers to produce maps for military, religious, and propaganda purposes. Often, these maps preceded empire, in that they showed both lands that were controlled and those yet to fall under the empire's dominion. Military expeditions into the modern era almost always included a cartographer to document the new acquisitions of the empire. These maps legitimated and codified power. They de-socialized conquest, erasing conquered

peoples and eliding the violence inherent in territorial acquisition. It goes without saying that maps were employed in these same processes during the era of colonialism and the conquest of North and South America, and they continue to be so employed today.

As representations of space, maps are necessarily reductive, excluding certain peoples and phenomena and emphasizing others. Historically, maps have been produced by and for those in power. As the tools of people in power, maps can serve to preserve the status quo or to create new spaces of accumulation and power. Maps and surveys facilitated the shift from feudalism to capitalism and the privatization of land ownership in Europe. As local rural areas were mapped at the behest of the wealthy to establish ownership, the small cottages and cabins of existing residents were frequently removed from these maps, legitimizing the claims of the mapmakers. The capitalization of agriculture and the global division of labor were both facilitated by the production and use of maps.

Other Types of Representations of Space

Maps, however, are not the only types of representations of space that have been produced by geographers.

Regional Studies and Cultural Analysis

In the first half of the 20th century, particularly in North America, the primary representations of space produced by geographers were of two distinct forms. The first was regional studies as proposed by Richard Hartshorne and formalized in *The Nature of Geography* in 1939. This form of representation divided the world into coherent, geographically distinct regions. The job of geographers, according to Hartshorne and others, was then to describe those regions and to firmly establish their uniqueness. This form of representation was most strongly associated with economic geography. The second dominant representation of space, this time associated with cultural geography, was the analysis of cultural landscapes and morphology as espoused by Carl Sauer and the Berkeley School. Like regionalism, these representations of space were largely

descriptive in nature. Sauer was interested in how different cultures manifested themselves on the land and altered their “natural” landscapes to fit their own cultural needs. In practice, this type of representation generally resulted in little more than chorology, as in the all too often cited example of counting barn types and mapping their diffusion.

The Quantitative Revolution

Beginning in the 1950s, the practice of geography began to move to yet another distinct form of spatial representation. Often referred to as the *quantitative revolution*, this movement represented a deliberate attempt to turn geography into a “spatial science” and redeem it in the eyes of the academy. The ideology behind this shift was positivism. Rather than focus on describing distinct regions or landscapes, this school of thought sought to discover the universal mathematical rules that dictated human movement and behavior in space. For this reason, space during the quantitative revolution was thought of as an undifferentiated isotropic plane rather than in terms of unique places or spaces. Representations of space were formulas or theories that could explain and predict the spatial activity of society. Theories and mathematical formulas were developed that harkened back to the locational theories developed by German geographers such as von Thünen, Lösch, and Christaller. These formulas and theories were valued when they were found to mirror real-world phenomena.

The Cultural Turn

Beginning in the 1980s, yet another shift in representation took place. This shift is often called the *cultural turn*. Largely based on the work of Continental European philosophers such as Lefebvre, Foucault, Saussure, Derrida, and many others, as well as British cultural studies, the cultural turn called into question the very possibility of representation. With the adoption of postmodern and poststructural theories, the field of geography was forced to acknowledge that any representation of space is by definition situated, limited, and reductionist. Geographers now attempt to position themselves within their particular representations and to position those

representations within the field of geography, thereby eliminating much of the illusion of authority associated with representations of space. They attempt to denaturalize the discourses and ideologies present in their work, making them visible and exposing the gradients of power inherent in any act of representation.

Not surprisingly, the representations of space produced during and after the cultural turn have been multifarious and complex. Some have marked a return to former representations, such as the rereading of maps for discourse or the current reassessment of cultural landscapes, while others have produced completely new representations of space. Actor-network theory, for example, represents space as an abstract series of networks connecting actors both living and inorganic in nodes of interaction that stretch infinitely outward across the globe. Many geographers today seek to represent space as it is experienced by groups found on the margins of most hegemonic discourses, be they racial, sexual, or cultural. In doing so, some now question the right of geographers to represent others or others' perceptions of space at all. Others have begun to challenge the primacy of vision in most forms of representation. Nonrepresentational theory and theories of practice seek to emphasize senses other than sight in the experience and representation of space. However, as Lefebvre noted, newer representations of space do not simply erase those that came before them. Today in geography, there are still many geographers who produce representations of space more akin to those associated with landscape morphology or the quantitative revolution. The rise of GIS, for example, is often represented as a continuation of the imperial practices of cartography and the abstract positivism of the quantitative revolution.

RESEARCH AND DEVELOPMENT, GEOGRAPHIES OF

Geographies of research and development (R&D) involve the study of spatial patterns and processes that emerge from the production of basic and applied research, on the one hand, and from how R&D activities articulate within the communities in which they are so deeply embedded, on the other. The significance of R&D in the current global context emerges from the critical role that technology and innovations have come to play in economic development. Intrinsic to understanding the significance of R&D is the need to appreciate the interaction between regions and economic processes and how spatial ideas such as distribution, arrangement, clustering, agglomeration, and so on, permeate the notion of interconnection and interdependence across space. A predominant characteristic of the current phase of globalization is economic restructuring resulting in deindustrialization and lay-offs, restructuring in the methods

of production, and the emergence of new manufacturing and service sector activities resulting from the emphasis on flexible production systems. This new mode of production has displayed a heavy reliance on new knowledge and on access to and processing of appropriate information. These ideas owe their debt to conceptualizations in Michael Porter's famous book *The Competitive Advantage of Nations*, where he established the relationships between high technology and competitive strategy in the wake of global economic restructuring. Porter's work provoked a new research agenda among those who were interested in regional economic development.

Contextualizing R&D

From a regional economic development perspective, the significance of R&D is that it helps enhance competitiveness and employment. As such, R&D indicators are seen as drivers of economic development. Indicators such as academic R&D, employment in high-technology establishments as a share of total employment, industry-performed R&D as a share of private industry output, net high-technology business formations as a share of all business establishments, R&D as a share of gross national product, and venture capital have been studied statistically to give operational empirical meaning to the geographies of R&D. However, in the literature on regional economic development, the term *research and development* has not been defined categorically. The closest that researchers have come is in terms of its indicators, while others continue to consider R&D as a subset of science and technology. In fact, there has never been a formal attempt by geographers, economists, or regional scientists to distinguish R&D from science and technology.

In the United States, from a federal government perspective, while the terms *R&D* and *science and technology* have been used interchangeably, they do not mean the same thing. There are two aspects of the government perspective: the military and the civilian. From the military angle, science and technology activities are a subset of R&D activities, while from the civilian angle, R&D activities are a subset of science and technology activities. From within the civilian side of

the federal government and in particular for departments such as NASA, DOE, and NSF, R&D activities are a subset of science and technology activities.

While some regions in North America, Europe, Latin America, and Asia have demonstrated their growth as technology-based economies (multimedia, biotechnology, health care, and other medical technologies), many others continue to lag behind. The development of any region as a technology-based economy depends on factors such as the R&D industry, the diversity of metropolitan areas, a sophisticated workforce, local sources of capital, and strong research universities. Thus, space has emerged as a basic organizing concept in understanding the geography of R&D. In the past few decades, the literature on R&D has grown to include a variety of theoretical and empirical works wrapped around overlapping and related concepts of local economic development, innovation, knowledge or learning regions, new industrial spaces, technology-based development, knowledge spillovers, the new economy, corporate complexes, social and human capital, and embeddedness, to name a few. It is in this context that most studies on R&D have focused on clusters and agglomerations.

Clustering and R&D

In light of the above, the observed geography of centers of R&D, also known as *knowledge regions*, has been thoroughly influenced by cluster-based strategies so that regional or local economic development may be achieved. This trend has been further bolstered by the idea of increasing returns to scale, embedded within which are notions of trust, loyalty, and partnership between firms. These concepts were central to the birth of Silicon Valley, Boston's Route 128, and the Research Triangle Park in North Carolina. Similar knowledge-based regions also emerged in Europe, such as Lombardy in Italy, Baden-Württemberg in Germany, Rhones-Alps in France, and Catalonia in Spain, and formed a loosely tied association to market themselves internationally as "The Four Motors of Europe." These technology-oriented complexes, or *technopoles*, have become famous for the impacts of the high-tech activities therein. Elsewhere, these

knowledge regions have also been conceptualized as the “new” industrial districts.

Partnerships and collaborations have emerged as the dominant feature in the growth of R&D due to the high initial fixed costs in the creation of services and the need for standardization as customers get “locked in.” For instance, writing a computer program for managing a client database is the same regardless of the number of clients or the number of copies that need to be reproduced. Furthermore, most software programs require compatibility with hardware, which means that there is a need for a partnership with ancillary service providers such as that between Microsoft and IBM’s SPSS (*Note:* SPSS was acquired by IBM in October 2009) or, for that matter, between car manufacturers using GPS technology and the producer of GPS. With the globalization of production and the concomitant problems associated with deindustrialization in the metropolitan regions of the United States, Canada, and Europe under conditions of neo-Fordism, the significance of R&D has increased manifold as local, regional, and national implications of the complex interactions of globalization are experienced. In fact, throughout the 1980s and 1990s, high-tech activities have emerged as a very significant factor of production, affecting spatial divisions of labor not only in the advanced capitalist countries of the world but also in the peripheral regions, thus bringing about spatial reorganization of the core economies.

The growth of high-tech activities complemented and fueled the flexible accumulation processes that were characterized by deregulation, flexibility, and decentralization. In fact, R&D has almost become the pivot of national and global stimulus worldwide. Operating at a number of spatial scales, R&D has been induced by many factors such as rising per capita incomes, the growing demand for health care and educational services, an increasingly complex division of labor, increasing international trade in services, and rapid growth in outsourcing service functions. Furthermore, the twin processes of decentralization and consolidation were informed by the inherent desire of economies to remain cost-effective with the use of new knowledge and appropriate information.

University Spinoffs and R&D

The role of strong research universities in technology-led economic development has emerged as critical throughout the growth of existing knowledge regions in the United States, Canada, Europe, and elsewhere. No longer are universities merely science-based monodisciplinary institutions providing degrees to their students; today, research universities have undergone dramatic changes under the impact of globalization and have become knowledge hubs providing services to technology-based enterprises and financiers, besides playing a new role as incubators of new science or technology-based enterprises. These kinds of activities have brought about a linkage between university research and high-tech activity, contributing to local economic development not only in the Silicon Valley, Boston’s Route 128, and the Research Triangle Park of North Carolina but also in other places. Top research universities such as Harvard University and Massachusetts Institute of Technology in the Boston metropolitan area, the University of California at Berkeley and Stanford University in the Bay Area of California, and the University of North Carolina at Chapel Hill, North Carolina State University, and Duke University in the Raleigh/Durham/Chapel Hill metropolitan area have all revealed how such institutions can contribute to the development of regional economic clusters. Similar high-tech activities have clustered in many leading metropolitan areas of other advanced capitalist countries of the world, such as Tokyo, Paris, London’s M-4 corridor, Seoul-Inchon, Taipei-Hsinchu, Singapore, and Shanghai, to name a few. It is within this context that today’s university-industry relationships have become symbiotic. Thus, the growing role of universities as centers of entrepreneurship has further evolved a dynamic interconnection between university, industry, and the government, also known as the “triple helix” model. In fact, so critical are universities in the articulation of regional and local economic development that even peripheral regions have begun to emulate conditions that are likely to attract a critical mass of high-tech activity so that local and regional governments can address the downward spiraling multiplier effects of deindustrialization in other parts of advanced capitalist countries.

In the United States, the Experimental Program to Stimulate Competitive Research (EPSCoR) has played a significant role in recognizing the relationship between high-tech activities and the state economic development function. The program was created in 1978 by a congressional mandate through the National Science Foundation (NSF) to support academic R&D in states that historically have been among the most underdeveloped in terms of not only their scientific and technical capability but also their capacity for economic development. While EPSCoR was created in the context of the proliferation of knowledge-based economies and an emerging mode of production called flexible specialization, a larger impact of economic restructuring has been that geographers have begun to ask regional policy questions largely under the impact of elasticity and competitiveness never seen before.

R&D and Spatialized Public Policy

Space itself has come to have a whole new meaning in a world in which digital technologies are having a tremendous impact on traditional notions of distance, region, location, and place, as well as spatial notions of distribution, clustering, agglomeration, and so on. Geographers and economists collectively began to ask questions such as the following: Why do some regions grow and others stagnate? Why and when does economic activity become concentrated in a few regions, leaving others relatively underdeveloped? How does technological change affect regional economic growth? What institutions and processes lead to advancement in technological change? Regional policy questions such as access to infrastructure and communications networks, the capacity to share information on these networks, differential access to information, and inequalities among the user base are all significant. These new concerns in regional economic development policy create opportunities and obstacles that shape how spatial policies will be designed. The role of spatial public policy has increased in the development of regions, since increasingly, local economic developments are associated with innovations. Even in a regime of flexible production, it was a spatialized regional development policy undertaking that created the Silicon Valley in California and other

outcomes such as the Third Italy, the knowledge region in Southern Germany, the scientific city of the Paris basin, or, more recently, knowledge regions such as Bengaluru—India's Silicon Valley. Thus, R&D has the capacity to change spatial economic structures.

RESILIENCE

The term *resilience*, as applied outside the discipline of physics, was originally developed as an ecological concept by Crawford Holling to describe the capacity of a system to maintain itself despite disturbances. He specifically used the term as a measure of an ecosystem's ability to absorb change and still persist, contrasting it with the concept of stability of an *ecosystem*, defined as the ability to return to a state of equilibrium after a temporary disturbance. Hence, an initial clear distinction needs to be made between two meanings of *resilience*: (1) a system's dynamics when

the system is close to equilibrium (termed by Crawford Holling *engineering resilience* and relatively identical to the stability property of systems); and (2) the dynamics of a system when it is far from any equilibrium steady state, called *ecosystem resilience*. The latter term is used interchangeably with other terms, such as *ecological resilience* or simply *resilience*, and it is the type of resilience that is discussed in this entry.

Although the theory of resilience is originally ecological in nature, it not only has immense applicability potential in the field of geography but also has been substantially enhanced through multitemporal and cross-scale geographical research. Given the resilience view of the world as a linked socio-ecological system organized hierarchically, the assimilation and further development of resilience theory in the various geographical subdisciplines can contribute not only to increasing unity in geography but also to cementing the role of geography in emerging research directions, such as sustainability science and global environmental change.

Broadly speaking, resilience theory conceptualizes systems as constantly changing, focusing on self-organization, reorganization, and renewal rather than stability, as well as scale, uncertainty, alternate state regimes and threshold effects, and nonlinear responses. With these ideas, resilience theory has changed how mainstream growth and efficiency are perceived both in natural and in anthropogenic systems. If the focus is solely on making growth more efficient, ecosystems and societies alike can become a lot more unstable and vulnerable to external shocks than when these are anticipated and internalized and the focus shifts to include necessary recoveries and reorganization phases. In short, resilience theory advocates that we view systems as governed by constant change, diversity, and multiple regime states and that we make flexibility, learning, and recovery the main components of system-level management and conceptualization.

More recently, the notion of resilience has begun to be used in a vague manner as a research approach to study multiscale and multitemporal social or natural changes or as a boundary object, a concept that facilitates communication across the borders of various scientific disciplines. As a result, resilience has become a complex and

multi-interpretable concept employed in an increasingly large range of interdisciplinary work regarding human-environment interactions. Another major conceptual distinction in resilience theory is between ecosystem/ecological resilience and social/socioeconomic resilience, but this divide is being bridged by the increased recognition of the linked nature of social and ecological systems, thus the term *socio-ecological resilience*. Despite the lack of established approaches to measuring resilience among the disciplines using the concept, Carl Folke has argued that managing for resilience in both ecological and social systems increases the potential of sustaining desirable pathways for development in environments subject to change, in which the future is hard to predict and surprise is likely.

Historical Perspective on the Development and Key Elements of Resilience Discourse

According to the *Oxford English Dictionary*, *resilience* is defined as (a) the act of rebounding or springing back and (b) elasticity. Departing from this mechanical concept and based on studies in the 1960s and 1970s of interacting predator-prey populations and functional responses related to the stability theory, the ecologist Crawford Holling documented in 1973 the existence of multiple stability domains or basins of attraction in natural systems. He illustrates their relationship to various ecological processes, disturbances, and spatial and temporal variability and heterogeneity. Supported by ecological research findings from various universities, the resilience approach began to influence fields outside of ecology, such as human geography, ecological economics, cultural theory, anthropology, environmental psychology, and other social sciences. Starting from the 1980s onward, the resilience framework became the foundation for work in active adaptive ecosystem management and was later strongly influenced by the theory of complex adaptive systems proposed by Simon Levin. Using large-scale studies of managed terrestrial, freshwater, and marine ecosystems, Holling and his colleagues described the cross-scale morphology of landscapes, which was later formulated into panarchy theory, that is, the notion of nonhierarchical systems of interaction.

In 1992, Holling introduced the extended keystone hypothesis, which postulates that important changes in ecosystem dynamics occur as a result of the hierarchical interaction across space and time, for a minimum of three orders of magnitude, of at least three key variables (and not more than five) that differ qualitatively according to speed. This hypothesis brought forth the concepts of slow and fast variables, and thus different temporal scales of analysis, which interact continuously with different spatial scales and heterogeneity to create multistable states, nonlinearities, and surprises in ecosystem behavior.

The description of these emergent system properties then led to the formulation of the heuristic model of adaptive renewal cycles by Lance Gunderson and Crawford Holling in 2002. Based on observations of ecosystem dynamics, the adaptive renewal cycle describes four phases of system development, separated by discontinuous processes and events, which repeat themselves continuously throughout the life cycle of a system and reemphasize the idea that disturbances are an inherent part of system development. In this model, the four periods are

1. periods of exponential change (the r , or exploitation, phase),
2. periods of growing stasis and rigidity (the K , or conservation, phase),
3. coexisting or complementing periods of readjustments and collapses (the Ω or release, phase), and
4. periods of reorganization and renewal (the α phase).

This model had enormous implications for natural resource management, which had conventionally been concerned only with the exploitation and conservation phases and had ignored the release and reorganization phases, also known in resilience as the *backloop*. This model and further work therefore introduced the idea of adaptive environmental and resource management, in which the key for managers was to learn to manage by change. They had to accept not only that change, surprise, and uncertainty are inherent in ecosystem dynamics but also that managers cannot afford to merely react to change but must expect it and learn to live and manage with it.

Terms such as *learning* and, later, *adaptation* became major components of the resilience discourse and practice. All the above models and concepts apply equally to ecological and social systems and in fact are being increasingly applied in other disciplines, such as sustainability science, economics, planning, political science, sociology, and the globalization discourse, at scales ranging from a farm to communities, cities, regions, nations, and the world.

Means of Building Resilience in Coupled Socio-Ecological Systems

Currently, despite the dilution of the meaning of *resilience* through the use of the term across disciplines, the overarching research and practical question is how to operationalize resilience. The first step in estimating or quantifying the resilience of a system is to specify the resilience “of what” and “to what.” The “of what” part includes specifying which socio-ecological processes and set of variables are of primary concern, establishing the boundaries of the system and the current regime, and determining at which spatial and temporal scales the interrelations in the system are to be examined. The “to what” part specifies to what exactly an ecosystem regime should be resilient, for example, the type, frequency, and intensity of the disturbance, whether human (prescribed burns, pollution pulses, deforestation) or natural (floods, hurricanes, volcanic eruptions, earthquakes). Steve Carpenter and his colleagues in the Resilience Alliance (a network of scientists actively involved in stimulating resilience research to inform the global policy process on sustainable development) have summarized, after nearly three decades of research, three major dimensions of socio-ecological system resilience:

1. The amount of disturbance a system can absorb and still remain in the same state or domain of attraction
2. The degree to which the system is capable of self-organization
3. The degree to which the system can build and increase its capacity for learning and adaptation

As such, resilience is one property that influences adaptive capacity, becoming a major component

in research aimed at devising the means of coping with and adaptation to global environmental change.

A resilient system is not necessarily in a desirable state from a management point of view; highly degraded systems can be very resilient and thus be trapped in a basin of attraction from which it is extremely difficult to extricate them. For example, a degraded savanna ecosystem that has shifted from a desirable open grassland state to an encroaching scrubland can be very difficult to return to a desirable state without major, long-term, and sustained management interventions. Typically, managers and practitioners aim to identify the “desirable” configuration for a system using historical analyses, traditional knowledge, or existing theories and maintain or enhance a system’s resilience in the face of climate, socioeconomic, political, or cultural change. The property of maintaining a system’s trajectory or altering its current trajectory to make the system more or less resistant to external disturbances is known in resilience as *adaptability*. However, when a system is in an undesirable state, as described above, and it cannot be returned to a known desirable regime, it can be transformed into a different system altogether, a property known as *transformability*.

Carl Folke and colleagues outlined two potentially useful tools for building resilience in socio-ecological systems, structured scenarios and active adaptive management, which require multilevel governance centered on learning and increased adaptive capacity and flexible and transparent institutions appropriate for the scale of management. Apart from the institutional aspect, building resilience also implies a drastic change in mentality, incorporated in four factors:

1. Learning to live with change and uncertainty
2. Recognizing and encouraging diversity irrespective of its form
3. A combination of types of knowledge and information to facilitate learning
4. Sustaining self-organization and cross-scale linkages and interactions

All the above elements work together to contribute to sustaining the adaptive capacity of a system, which is related to biodiversity, genetic

diversity, and landscape diversity in ecological systems and adaptive, open, and multifunctional institutional and networks in social systems.

A successful combination of resilience-building tools and strategies can lead to increased resilience and minimization of system vulnerability, of which resilience is a major component along with exposure and sensitivity. An effective approach to increasing resilience can further contribute to increased sustainability by creating (a) a policy that recognizes the strong interrelationships between the biosphere and society and (b) the necessary framework of cross-scale collaborations to achieve resilience and long-term sustainability. Although the main criticism of resilience science remains its lack of straightforward operationalization and quantification, the underlying science is indisputably accurate, and the potential for significant contributions from the field of geography is immense.

RESISTANCE, GEOGRAPHIES OF

Geographers' use of the term *resistance* refers to three different, but interrelated, arenas of research: (1) social movements, (2) social protest, and (3) everyday and psychic forms of resistance. Thus, while the word *resistance* is something of a catch-all term and carries considerable intellectual baggage, it has come to serve as a useful mechanism by which a variety of different approaches to the study of social conflict, opposition to domination, and the assertion of power can be understood.

What unites all such seemingly disparate studies is the key belief that not only is the study of resistance critical to understanding social and cultural change, but also all geographies are forged by a negotiation between methods of control and modes of contestation. In other words, geography is not a fixed “backdrop” to social life but instead is a transformative agent in itself. Thus, the *where* of resistance is important—though this might equally be in a figurative, psychic, or virtual space—but of equal consequence is the fact that resistance is always mobilized *through* spaces and is thus shaped and given meaning by geography. Conversely, as the term *social movements* implies, resistances generate reconfigurations of spaces as the *actants* (humans as well as other nonhuman “things”) and meanings move. For example, after the revolution of 1789, the Parisian Bastille was

understood no longer as a space of oppression but instead as a symbolic place of liberation. This spatiality is often rather more complex and multi-layered, with resistances generating multiple and constantly shifting meanings. A capital-intensive factory, say, can be transformed without the knowledge of the management into a space of dissent by workers' feigning ignorance over quality procedures. In whichever way it is manifested, resistance is a profoundly spatial project. This entry first describes the development of geographical analysis addressing resistance. It then reviews some of the criticisms of this concept as it has been used in geography, as well as current research that has emerged in the wake of such critiques.

Evolution of Geographies of Resistance

The concept of resistance, while having a long intellectual history in the broader social sciences and humanities, is a relatively new field of study for human geographers. Thus, while historians and sociologists have long studied the iconic American and French Revolutions of 1775–1783 and 1789, respectively, geographers' interest is more recent. While it is possible to locate traces of interest in geographies of resistance before the 1970s, most notably in the work of the 19th-century geographer Élisée Reclus, the so-called radical turn brought the study of class struggle and urban social movements firmly to the fore of human geographical research. Central to this new enthusiasm were the armed struggles in several developing countries, the riots in American ghettos in the late 1960s, and the student riots in Paris—and elsewhere—in the spring of 1968. Against such pressing problems, the abstract mathematical modeling of spatial science seemed extraordinarily socially inert.

Meanwhile, “historians from below,” most notably Christopher Hill, Eric Hobsbawm, George Rudé, and E. P. Thompson, had, through the application of Marxist theories, blazed a trail in the study of popular movements. Marxism's central acceptance of the Hegelian concept of dialectics positioned social conflict as something central to all societies and thus, by definition, to the study of human geographies. Class conflict, as many Marxists would suggest, is not only the inevitable product of dialectical tensions between

the bourgeoisie and the proletariat but also the result of the dialectical emergence of “antisystems” in opposition to the institutionalized state. This understanding that societies are never inert but always volatile due to their composition of competing social groups and diametrically opposed class interests necessarily places a strong degree of emphasis on revolutionary change and associated social movements. David Harvey’s *Social Justice and the City* (1973), the book that blazed a trail in applying Marxist thought to the study of geographical change, offered a rather more nuanced approach. Indeed, the beauty of Harvey’s book—and the key to its huge intellectual influence in the discipline—was that, as it displayed Harvey’s structuralist understandings and belief in the pursuit of one united democratic socialist movement, it offered for the first time a geographical take on Marxist thought. Moreover, its analysis of the North American city highlighted not potentially revolutionary actions but, instead, the resistances offered to the white, upper-middle-class political and economic hegemony.

Notwithstanding the importance of *Social Justice and the City*, there was no sudden surge in studies of resistance. Indeed, few of the possibilities suggested by Harvey’s analysis were fully explored by geographers at the time. With the arguable exceptions of the early work of Andrew Charlesworth and David Sibley, most geographers adopted a more straightforwardly Marxian analysis centering on collective labor organization and class struggle. Thus, while the rich possibilities for researching geographies of resistance were now well understood, they were not widely adopted. Moreover, the field was fractured between those engaged in historical research and those working on the there-and-then. Indeed, while many radical geographers often sought to open their students’ minds to the world of resistance by turning to a copy of E. P. Thompson’s *The Making of the English Working Class* (1963)—a textual talisman to social historians and historical geographers—they more often than not failed to make parallel connections to what their historical geography colleagues were doing.

The concurrent emergence of postcolonial studies and feminist geography in the late 1970s and early 1980s helped renew interest in the less dramatic, more everyday forms of resistance. The

shared perspective of the study of the ability of nondominant groups to survive under—and even challenge—conditions of domination placed a greater emphasis on the ability of repressed individuals and groups to mobilize alternative ideologies in forging new social worlds. Such acts of resistance, so this perspective suggests, can take many forms, not all of which have any visible manifestation, for instance, mental resistance to psychic domination. Moreover, while some such protests might be recognized by oppressors as deliberate acts of resistance, other acts might either not be recognized (e.g., false compliance) or not be considered believable (e.g., anonymous political placards created by supposedly apolitical slaves). Thus, while such resistances are necessarily motivated in response to a dominant power, they might not always seek to rebalance power relations.

It has not escaped the attention of geographers that this analysis bears a strong resemblance to the work of the anthropologist James Scott. The central premise of Scott’s seminal *Weapons of the Weak* is that while individual acts of insubordination and evasion make no headlines, thousands of such acts create their own barriers of resistance, just as millions of polyps create a coral reef. The spatiality of such protests inevitably occurs, so the analysis goes, within the realm(s) of domination, which, in the case of Scott’s thesis, were the plantations of northwestern Malaysia.

This relationship has been called into question on two central counts. Michel de Certeau has asserted that the “tactics” of resistance come from a place outside the practices of domination but seek to “insinuate” themselves into the realm of domination. Resistance thereby occurs in—or between—the fault lines of power, spaces beyond conventional surveillance—or, as Edward Soja labeled such “gaps,” *thirdspace*. It is important to note, though, that according to Foucault, as we all internalize the systems of surveillance used to assert power against us, there are no gaps. Resistances occur, therefore, when we reject our self-surveillance, a shift that is without bounds yet is not aspatial. What does not differ between Scott’s and Certeau’s analyses, though, is the shared emphasis on the malleability of identity. Individuals can take on multiple personas to suit different situations, for instance, false deferential efficiency in the company of management or

Some 10,000 people take part in a demonstration against the International Monetary Fund and the World Bank meeting, September 27, 1988, in West Berlin. Banners state the demonstrators' belief that credit policies by the industrialized nations threaten the Third World.

foot-dragging resentment at other times. They might also assume an identity as a tool of resistance, for instance, as vegetarians in opposition to factory farming, or use their identity as a position from which to protest against societal attitudes. Of course, the assumption of an identity does not necessarily need to occur in response to a local context. Indeed, mass (international) media and forms of electronic communication, not the least the Internet, have allowed for the distancing between the “event”/“power” that is being resisted and the “act” of resistance. Being there and being known can be an irrelevance. As the recent worldwide protests over the repressive policies of the Burmese (Myanmar) junta have highlighted, resistances can occur outside both spatial and experiential contexts.

Critiques of Geographical Concepts of Resistance

Through such understandings and intellectual positions, resistance became one of the key topics of the so-called cultural turn in human geography. The concept was not, however, without critics. In particular, the tacit acknowledgment that signs of resistance could be read in all acts—the choice of one brand over another being a protest against a corporation, a raised eyebrow a personal slight—has been called into question. The first substantive challenge was raised, albeit implicitly, by Tim Cresswell's research on the spaces of transgressive practices. The conclusion from the case studies in Cresswell's *In Place, Out of Place* is that while to resist is intentional, to transgress is often unintentional, the

crossing of a border/line that has no sign or meaning to the “perpetrator.” The act, though, still functions as a form of protest, for all transgressions are judged by those who react to the practice. To resist, conversely, requires the actor alone to make a judgment. As such, reading bodily practices as acts of resistance—or otherwise—requires keen attention to both the sociolegal and the spatial contexts in which the practice is performed.

Another critique was issued by those who not only queried the worth of such an all-embracing concept—if everything could be considered to be an act of resistance, what is left for other human geographers to study?—but also by those who found such definitions lacking in political meaning. Indeed, political geographers have questioned whether some distinction ought not to be made between, on the one hand, political struggles and, on the other hand, cultural politics and personal resistances. This is not to deny the power or importance of such alternative forms of resistance but instead is an acknowledgment of the increasing political potency and power of social movements in the late 20th and early 21st centuries. Indeed, within the past decade, there has been a discernible shift to empirically rich studies of indigenous people’s movements in the developing world and anti-corporate/globalization protests.

Directions in Current Research

While this trend has clear resonances with earlier studies within “radical geography,” recent research has been sensitive to the ways in which current movements often use a range of tactics that combine overt protests and political demonstrations with other techniques that are not easily understood as being “organized.” For instance, Paul Routledge has described the anticorporate, antiglobalization forum People’s Global Action not as an organization but instead as a “convergence space” of other groupings whose primary function is to *inspire* acts that oppose corporate domination. Such groupings often rely on the “flattened” hyperlinked spaces of the Internet to allow action to be negotiated in non-hierarchical, democratic ways and thus allow for oppositional tactics to be developed in secret through encrypted e-mails. In a sense, therefore, if Soja’s thirdspace meaningfully exists, a strong argument could be made that it is the Internet.

Routledge’s concept of heterogeneous global grassroots “networks” also acknowledges that resistances invariably rely on and often directly critique the social enrollment of nonhuman things. For instance, the so-called Luddite protests of the 1810s primarily attacked job-supplanting machinery rather than the machinery owners. Moreover, actor-network theory suggests that since the world can usefully be described as a network of all things—animals, machines, plants, buildings, money, people, and so on—where power and meanings are generated by the relationship between things, then resistances are given form by the nature of the links in the network.

RESOURCE ECONOMICS

All production and consumption require the use of natural resources. Resource economics seeks to determine the optimal extraction rate of these resources. Key to the determination of optimality is the need for extracting firms to balance the benefits that accrue today against the costs and benefits of leaving the resources for a later time.

Resource economists propose that nonrenewable resources should be valued differently from goods that can be regenerated or produced, because the former can be extracted only once. Developing this idea further, Harold Hotelling showed that the *scarcity rent* rate, which is the opportunity cost of using resources today, would rise at the rate of interest. The limited ability of renewable natural resources to regenerate themselves and the potential for stocks to be depleted below recovery levels need to inform their use over time. Depending on the resource type, various rules for optimality have been derived, such as the Faustmann rule for forestry resources or the concept of maximum sustained yield for fisheries. The Faustmann rule determines an optimal timber resource rotation age through optimization of the net present values of all revenue flows; it states that an optimal rotation age will occur when the marginal benefit and marginal cost of delaying harvest are equal. Similarly, the maximum sustainable harvest for fisheries assumes a steady-state stock size, which occurs at the point where the net natural growth rate is at its maximum. This point is called the *maximum sustained yield*.

Issues in Determining Optimal Extraction Amounts

Nonrenewable resource models have been criticized because little empirical support exists for the Hotelling rule and in part because, as Matthias Ruth suggested, the model does not account for individual firm characteristics. Renewable resource models have been criticized for their inability to provide meaningful advice to resource managers, as well as for how resource economics values the benefits provided by natural resources. Renewable resource models vary according to the biological characteristics of the resource. For

instance, biomass stock models for fisheries are a function of species population, carrying capacity, and growth rates. However, growth rates, selling price, and efficiencies of fishing operations, as well as other biological factors, are typically considered exogenous in calculating the optimal harvest for renewable resources; because of their noninclusion, the applicability of the models for use by resource managers is limited.

Costanza and Daly proposed that renewable resource ecosystems not only yield goods through their harvest but, if left in place, provide services as well, such as erosion control or water catchments. In choosing an optimal extraction path, the costs of extraction, including the impacts on the local environment, have been largely explored. However, the benefits of leaving the resource in situ have predominantly been ignored, and ideally, the costs and benefits should be calculated simultaneously.

It has been argued that in calculating an optimal extraction path, the impacts of human actions on ecosystems are often overlooked. For example, the impact of the intensity and duration of extractive actions are not accounted for in calculating annual extraction amounts. It is possible, under one set of assumptions in which the needs of an ecosystem are overlooked, to arrive at an extraction path that is spread over many years, placing constant pressure on the resource. Alternatively, taking the ecosystem's needs into consideration, a more intensive extraction path may be selected with less overall disruption to the natural habitat.

Due to the long-term nature of resource extraction, future profits are typically discounted to facilitate the identification of intertemporally optimal extraction paths. The discount rate reflects an individual's time preference, which captures tolerance of risk and uncertainty, as well as the impacts of technological progress on resource discovery, extraction cost, recycling, and the creation of substitutes. There is controversy in discounting future profits because of intergenerational equity issues and the assumption that technological progress tends toward cost and resource savings. Robert Solow argued that present generations should be allowed to extract more of a resource because future generations, due to technological progress, will be able

to do more with less. Alternatively, Robert Costanza and Herman Daly suggested that individual behavior in the short run is inconsistent with long-run best interests for both the individual and society, as people are misled by short-run reinforcements of current behaviors that may come, for example, from monetary incentives, social acceptance or admonishment, and physical pleasure or pain. Consequently, instead of using a private discount rate, public policy decisions to guide resource extraction should be based on a much lower social rate.

Resource Economics: Past and Future

Many resource management and extraction models were developed with the goal of preserving and managing natural resources for future generations. Over the past century, these ideas have continued to develop and expand, as shown by the growth of subfields of economics such as resource and environmental economics and the intermingling of conservation and economic growth under the paradigm of sustainable development. In fact, managing economic growth through sustainable development has emerged as a methodology in itself, transcending multiple disciplines and giving rise to ecological economics.

The role of government in resource management is likely to increase for two reasons. First, if, as Costanza and Daly suggest, a discrepancy exists between our short-run behavior and long-term best interests, there is a need for intervention to guide sustainable development; second, with the expanding scale of resource management issues in the international arena, governments will likely take on a larger role. However, management and extractive issues, when managed at an increasingly global level, will require a better understanding of microlevel firm and individual behavior.

Robert Deacon and colleagues have suggested that the role governments play in regulating natural resources, including the policy tools chosen and the nature of a firm's responses, is largely a black box; to address this shortfall, future modeling efforts are likely to include more historic and institutional variables. Other subfields, such as development economics, that have experience with these variables offer a platform from which

to analyze policy interventions, while also providing case studies for policy implementation.

RESOURCE GEOGRAPHY

The study of human valuation and use of Earth's materials lies at the core of the modern discipline of geography. Indeed, investigation into the character, production, and distribution of natural resources might be said to be a quintessential pursuit for a discipline that has in large part been fashioned on the relationships between humans and their environment. Linked to political geographies by concerns over territoriality and proprietorship, to economic geographies through networks of production and consumption, to social and cultural geographies by collective practice and meaning making, and to environmental geographies through

the modification of natural systems, the study of resource geographies requires consideration of both the “human” and the “physical” sides of the discipline. As such, it is well conceived as a specialty where contemporary disciplinary concerns over the constitution of socionatural assemblages might profitably proceed.

This entry presents three broad imperatives that have marked natural resource investigations during the development of the modern Anglo-American discipline: (1) the creation of imperial inventories, (2) the management of natural capital, and (3) the analysis of political-economic systems and political-ecological networks. While each is a part of a genealogy of scientific engagement with the stuff of Earth, the respective imperatives identified here have differentially marked resource studies in geography during succeeding phases of the discipline's history. The imperial inventory period spanned the late 18th through the early 20th century; concerns over the expansion and management of natural capital took center stage in the middle to latter decades of the 20th century and persist today; and efforts to deconstruct and analyze the political-economic and political-ecological networks that produce natural resources became a preoccupation in the decades leading up to the turn of the 20th century and continue into the 21st. Thus, in presenting an overview of each period and the dominant imperative driving natural resource study, the aim of this entry is to situate the development of the subfield of resource geography within the broader context of the changing intellectual terrain of the discipline as a whole.

Empires and Resources

The roots of the modern discipline were born of European exploration and empire. First in the service of the Enlightenment ideals of scientific discovery and human progress and then in aid of 19th-century colonialism and commerce, the geographers and other scientists who served Europe's kings and queens compiled vast catalogs and accounted for the distribution of the flora, fauna, topographies, and climates of faraway places. Embodied by men such as Alexander von Humboldt, Charles Darwin, and the scientists sailing under Captain James Cook, geographical study of Earth's resources in the late 18th and

early 19th centuries was dedicated to uncovering the character and complexity of Earth and communicating the knowledge thus produced to audiences in Europe.

Contemporary reviews of this early history of the discipline have called into question the tendency to regard the period of Enlightenment exploration as benign in its environmental and cultural effects and therefore morally superior to the period of colonialism and commercial exploitation that would emerge in many European overseas possessions as the 19th century wore on. Rather, recent scholarship has demonstrated that the representations (journals, reports, paintings) produced by scientists to communicate the environmental qualities of far-off territories to decision makers in imperial centers served to initiate the construction of those territories as potential spaces of capital accumulation through resource extraction. Thus, by the early decades of the 19th century, a European sense of the value of the various parts of the Earth was being discerned through the eyes and instruments of scientists who were charged with simply uncovering the true nature of the Earth.

Exploration and empire were seldom far removed from one another, however. From Napoleon's armies of geographical scientists in Egypt to the British efforts to map the Indian subcontinent, the production of knowledge of environmental resources by trained scientists formed a central front in the effort to control territories claimed by other peoples. With this knowledge, both governance and capital accumulation through resource extraction became possible for the imperial powers. In the case of North America, this project of colonial resource cataloging was engaged well past the ending of formal colonial relationships and the advent of federated nation-states. In the western portions of North America, government-sponsored scientific expeditions were mounted in the late 19th century to ascertain environmental characteristics and the possibilities for commerce and settlement. Political leaders in the long-settled and urbanized areas of Eastern Canada and the United States viewed western territories as natural extensions of national spaces and understood their environments to be unclaimed and awaiting exploitation by a young and industrious settler society. Thus, parties were dispatched, often with Native guides, to lands unknown by the members

of settler society. Under the guidance of experts trained in the geographical sciences, these parties were charged with recording topographical characteristics, noting the irrigation potential, surveying timber stands and mineral deposits, and generally going about the business of constructing as complete a natural inventory as possible of as yet unsettled lands.

The knowledge produced by such survey parties served to construct particular resource geographies for particular peoples. In recounting the experience and legacy of John Wesley Powell's surveys of the Colorado Plateau in the 1870s, a recent study notes the enterprise's effect of both emptying the landscape of its Native inhabitants and rendering its nature visible to decision makers in Washington, D.C., such that settlement and irrigation policy might be set. In the Canadian context, researchers have noted similar colonial effects flowing from the work of the geologist George Dawson on the west coast of British Columbia. However, in this case, minerals, rather than water, formed the resource of interest. Location and resource aside, such work demonstrates that the production of knowledge about the resource base of western territories preceded and ultimately facilitated colonial settlement by the two young nation-states.

Managing for the Nation

As the 19th century ended and the 20th began, the identification and description of natural resources by geographers shifted in emphasis away from colonial cataloging and toward the service of the nation-state's social and economic development. In response to two world wars, the dust bowl of the 1920s, and the Great Depression of the 1930s, governments in North America were faced with co-coordinating economic recovery and survival for citizens and corporations alike. To this end, experts, working in universities and beyond, were enlisted by government agencies to tackle environmental problems of regional and national importance—the decline of forest and fish stocks, soil erosion, uneven water availability, the lack of energy resource security, and so on. In this climate, geographers found themselves called on to contribute to the management of public natural resources, often by providing “statistical pictures”

of inventories and distributions as well as analyses of the efficiency and sustainability of levels of exploitation of particular materials. The geographer as a useful scientist was given the chance to shine—a characterization cherished by the discipline, particularly in the years following World War II. Under this imperative, geographical study of natural resources was, and in many quarters continues to be, regarded as central to the progressive development of the liberal democratic nation-state and the social and economic well-being of its citizens. Through the deployment of a range of geographical techniques and tools, from field observation to geographic information system (GIS) modeling, geographers have a long history of helping states and their citizens manage their natural resources for collective social and economic goals.

Critical Approaches

Recent work in geography has noted the considerable authority wielded by scientists in presenting a complex “statistical picturing” of the natural inventory of the Western United States and Canada in the Progressive Era of the early 20th century, as well as the power of that authority to shape the making of social, economic, and environmental policy. From this period through to the present, and with a relative confidence in the ability of scientific inquiry to assist in more efficient and sustainable resource use, geographers have mobilized their skills in cartography and the natural and social sciences to address issues of resource distribution, health, and sustainability. However, a critical strain of analysis has emerged alongside the more classically liberal imperatives that have marked the managerial approach within the discipline. For several authors, the contested definition and use of natural resources demands consideration of who wields the authority to represent nature's character and toward what end. Thus, recent papers in geography journals have pointed to exclusions in the scientific, managerial, and political ranks along the lines of both gender and race. And, as a complement to the consideration of the politics of identity and representation, the critical literature has also highlighted the ways in which the production of natural resources has

been embedded in colonial projects and capitalist socioeconomic relations that have led to marginalization and oppression.

As the studies mentioned above in reference to colonial cataloging indicate, European scientists encountering New World environments effectively represented them in terms consistent with modern Western worldviews. Research conducted on late-20th-century resource management in Canada and Australia reveals that Eurocentric ways of knowing continue to dominate resource management across the former British settler colonies at the expense of Aboriginal populations, who are steadily regaining territorial and self-governance rights. Proponents of a more culturally diverse approach to resource management argue, in part, that in light of the environmental deterioration that has been allowed to occur under modern scientific regimes, humility demands that attention be paid to and lessons be learned from the localized environmental knowledge and durable social, political, and economic systems of the Aboriginal peoples. Given the rise in Aboriginal political power over the previous generation and considering that many Native peoples' territorial claims conflict with the established resource rights of non-Aboriginal parties, the insights offered by this stand of critical resource scholarship demand attention.

While a rather large literature has developed on issues of culturally specific ways of knowing and managing resources, less attention has been paid to the place of gender in the scientific and managerial ranks. As the few papers that address the issue make clear, however, the study and management of environmental resources has historically been a male domain. Identifying the masculine images of the hearty field scientist and the idealized laboratory scene of the rational man in the long white coat, critics argue that the very practice of geographical (and other) science has been constructed as a male endeavor. Additionally, this area of research in resource geography has demonstrated that the environmental concerns held by women are rarely accorded attention by resource researchers and managers; issues of family health, quality of life, and social justice (in this formulation constituting a set of socially constructed feminine concerns), critics claim, are ignored on the

altar of economic efficiency and competitive capitalism (in this formulation constituting a set of socially constructed masculine impulses and institutions). As with the demand for inclusion of Aboriginal voices and perspectives in resource study and management, the call for greater gender diversity has resonated ever more loudly over the previous generation and, it would seem, can no longer be marginalized.

In the literature that addresses identity and the politics of representation in resource geography, management at the level of the community is often identified as desirable. Implicit within this stance is the idea that state-level management is too detached, bureaucratic, and hierarchical to respond effectively to local social and environmental conditions. Researchers have responded by investigating community efforts at managing local resources. While several studies have uncovered examples of increased economic diversity, greater community control and pride, and enhanced environmental stability resulting from local management arrangements in the North American West, others have noted the challenges encountered by some communities that have taken on significant resource management responsibility. In particular, both the capacity (though capitalization, managerial skill, technical expertise, etc.) and the credibility (in terms of inclusion, interests, and obligations) of local communities to engage in sustainable resource development have been found to be uneven. Linkages to national and global political-economic systems, this literature suggests, can at times render local communities unable to effectively manage natural resources. Thus, the idealization of community resource management needs to be tempered by an understanding of the multiscale networks that mark modern resource economies.

A separate, yet related, strand of critical scholarship in resource geography has uncovered the relationships between capitalist production and resource landscapes at a variety of scales, from the regional to the national. This literature has considered the development of natural resource geographies in terms of both environmental impacts and social effects. On the one hand, treating the materials of the Earth as inputs in a system of production, work in this area has traced the ways in which the profit motive has intersected with the

limits of natural systems, both renewable and nonrenewable, to produce environmental degradation. Alternately, other studies have focused on the distribution of the wealth derived from the production of resources and analyzed the resultant phenomenon of uneven development within and between societies. In each case, however, the analyses share an approach, rooted in Marxist political economy, that treats capitalism as an overarching influence that draws bodies and materials scattered across space together into productive relations that have concrete social and material outcomes. In this way, the literature emphasizes the extralocal forces that intrude on efforts at community management of resources.

Dissatisfied with the rigid structuralism of political economy approaches to resource geographies, several authors have recently attempted to untangle the ways in which individual actors and environments are engaged by and engage with the overarching framework of capitalist resource production to produce unique political-ecological arrangements. Of particular interest to researchers has been the rise of neoliberal economic ideology (a hyperfetishization of “the market” and a corresponding distrust of the utility of government) and its engagement within resource policy and management circles. Work in this area has shown a remarkable diversity of community response to proposals to deregulate resource industries from fishing to forestry, with successful outcomes (social and environmentally sustainable practices) resting as much on the capacity and credibility of communities to engage national and global markets as on their ability to re-regulate resource management in the context of local circumstances and desires. By highlighting local actors and environmental characteristics and their reciprocal relations with overarching structures such as capitalist political economies, work in the poststructural vein points to the complex and multiscale social and environmental networks that make up present-day resource geographies.

Conclusion

As this overview indicates, the area of resource geography is broad, encompassing many subdisciplines of geography. As such, it has formed a central concern throughout the history of the

modern discipline and in many ways mirrored geography’s ever-shifting political and intellectual commitments. Marked by succeeding, yet overlapping, imperatives driven by those commitments, the study of natural resources by geographers has shifted from serving as an imperial cataloging enterprise to providing a position from which to critically evaluate the interconnections between cultures, politics, economies, and environments. Thus, in a discipline often divided between “human” and “physical” concerns, the study of resource geographies provides an opportunity to bridge the nature/culture dualism that so permeates our lives.

RESOURCE MANAGEMENT

See Environmental Management

RESOURCE MANAGEMENT, DECISION MODELS IN

There are a wide variety of natural resource management issues that are addressed using a suite of different management tools. Primary among these are decision models. Natural resource management problems include developing structures and procedures to provide reliable water supply for domestic and industrial use, irrigation, recreation, and flood control; ensuring that productive wetlands are preserved and maintained; providing conservation lands to ensure maintenance of biodiversity; managing air and water quality; and fisheries management, among many others. A wide variety of decision models are also available to address these issues, ranging from simple sequential pairwise comparisons of options to more sophisticated models requiring vast amounts of data and computing power. Decision models help generate plausible alternatives for action and help choose among these alternatives. There are also many ways to categorize these decision models; Figure 1 provides a brief typology.

A decision problem for natural resource management can consist of the overall goals (objectives) for wise management—for example,

providing a “safe yield” of a renewable resource to ensure its sustainability or efficiently using a limited natural resource such as fossil energy. The discrete choices to be made are the alternatives (e.g., which forest stands to harvest, choosing among multiple reservoir projects, choice of fuels for generating electricity). For each of the alternatives, several attributes may be important for the decision (e.g., in the case of conservation lands, this may be their cost, location, and habitat value for different species). The discrete choice models in Figure 1 differ as to whether a single criterion or multiple criteria are used and if time sequencing and uncertainty are major factors.

Cost-benefit analysis has been long and widely used, particularly for large-scale, publicly funded projects in water resource management and in environmental regulatory decisions. When choosing among alternative projects, procedures, or standards, the monetary costs and benefits for all attributes of each alternative are established. The choice is based on the maximization of a single objective: economic efficiency. This requires choosing the alternative whose net benefits (total benefits – total costs) are the largest. To account for a time sequence of costs and benefits, discounting (valuing all benefits and costs in current dollars) is used. A difficulty in the use of this technique involves the valuation of all attributes for all alternatives, especially benefits, particularly when they are not traded in the markets.

Multi-criteria evaluation (MCE) decision models have been used when more than one criterion (objective) is employed and/or when the attributes for each alternative can be measured in their natural units, obviating the need for strict valuation. Often, the measures of the attributes for each of the alternatives are standardized. This is usually linearly scaled from 0 to 1 or 1 to 100, or through the use of value functions or fuzzy set functions, with the purpose of allowing fair comparison among the measures. The criteria (or objectives) are then weighted using the decision makers' preferences. A weighted linear combination is obtained for each alternative by summing the product of the criteria importance weight and the alternatives value on each of the attributes; the decision rule then is to choose the alternative having the largest value. These weights can be elicited directly by simply assigning weights,

Figure 1 A brief typology of decision methods for natural resource management
Source: Author.

through structured transitive comparisons (multi-attribute utility theory, or MAUT), or by making a series of pairwise comparisons of the alternatives (the analytic hierarchy process, or AHP).

If the resource management decision involves several sequential choices, and uncertainty is part of the process, decision analysis is often employed. The decisions are formulated in a “decision tree,” with objective or subjective probabilities at specific nodes of the tree representing the chance occurrences. The optimal prescribed decision sequence is the path along the decision tree providing the largest expected outcome.

When the resource management choices are continuous, or there are too large a number of discrete options, decision models based on mathematical optimization are often employed (called mathematical programming models). The generic structure of these models has a mathematical function that is to be maximized or minimized (the overall objective for the decision process), comprising variables that represent the decisions that are to be made and constraints that describe the natural resource system or restrictions on the optimal solution (such as budgets or physical limitations). Mathematical programming models can have a single objective or, similar to MCE models, can have multiple objectives—and incorporate the relative importance weighting schemes mentioned above. They often form part of a comprehensive decision support system (DSS) composed also of integrated programs for data collection, manipulation, analysis, and display (i.e., geographic information systems, or GIS, and remote sensing). These programs may often have provisions for participation of communities that may be affected by the resource decisions; an example is the “Shared Vision Planning Framework” developed by the U.S. Army Corps of Engineers.

Applications of mathematical programming models and DSS have been extensive in natural resource management. For example, there are numerous mathematical programming models designed to assist in decisions concerning the number, locations, sizes, and operating characteristics of water reservoirs that must meet residential, commercial, irrigation, and industrial water supply needs and also provide for recreation uses and flood control (multiple and often conflicting objectives). Other programming

models are used to determine the optimal time and space sequencing of dredging operations on economically important navigation channels. These types of decision models have also been used in forest management to prescribe optimal cutting patterns to ensure ecologically and economically sustainable forests; in fisheries management to prescribe optimal control mechanisms, limiting the number of fishing vessels and fishing days, specifying the type of gear, and restricting fishing areas; and in conservation planning to choose an optimal pattern of land acquisitions to preserve biodiversity under competing ecological and economic objectives.

RESOURCE MAPPING

Resource mapping refers to the cartographic depiction of natural resources such as land, water, soil, minerals, forests, biological species, wind power, and so on. Thus, the phrase refers to the process of acquiring, analyzing, representing, and presenting information about the geographic distributions of these resources. The resulting resource maps visualize the spatial variation of the resources being mapped and are a means to analyze and store such information. The spatial variation information is fundamental to inventorying, monitoring, and modeling the resources; therefore, mapping is usually a key operation in resource management, conservation, use, and planning. Resource mapping is a routine practice in many governmental and non-governmental agencies or organizations.

The history of resource mapping may be as long as the history of the map itself. It is not hard to imagine that our ancestors used graphics to indicate the locations of water sources or to keep records of the sizes and shapes of lands. An example of modern resource mapping is the Canada Land Inventory of 1963–1995. This project was a massive effort begun by the Canadian government in the 1950s to identify the nation's land resources as well as their existing and potential uses. What makes this project particularly significant is that it developed the first geographic information system (GIS), the Canada Geographic Information System (CGIS). The development of this system was motivated by the need to accurately and quickly measure land areas.

Nowadays, modern geospatial information technologies, including GIS, remote sensing, and the global positioning system (GPS), have revolutionized the process and output of resource mapping. Remote sensing may provide data that are both spatially and temporally detailed and often cover vast areas and long time spans. A GPS can accurately and precisely associate ground sample data with remotely sensed data, so that models can be built to translate the data obtained through remote sensing, for example, a vegetation index, into the information about resources, for example, vegetation type. A GIS is the platform and tool to integrate all kinds of data, build and run models, and design and create the final maps.

Figure 1 shows a map generated through the integration of these modern technologies. The map shows the spatial distribution of biomass resources that are usable for energy production in Guangdong Province, China. The calculation of the amount of usable biomass at each location started with remotely sensed data, including MODIS/Terra and LandSet. The remotely sensed data were processed in a GIS by a series of physical, biological, economic, and ecological models built based on ground samples (located by a GPS) and the literature, to derive the usable biomass value at each location and generate the map. With this biomass information and the information about a road network (also shown in the map), further modeling can be performed to evaluate the feasibility of establishing biomass electric power plants in this area and locate optimal locations for such plants based on transportation costs.

Besides the adoption of the modern spatial information technologies, another trend in today's resource mapping is the shift from vector to raster format to store, represent, or display spatial data in digital form. The data for today's resource mapping, as exemplified by remotely sensed data and digital elevation models (DEMs, which are being increasingly derived from remotely sensed data), are increasingly available in raster rather than vector format. The implication of this data format change is more profound than simply how the data are organized and stored. The capability of raster data to accommodate high resolutions in both spatial and attribute aspects facilitates the representations of continuities in both geographical and parameter spaces, which in turn facilitates the application of new modeling methods, such as fuzzy (continuous) classification, in resource mapping. In *fuzzy classification*, an object can belong to more than one class and is not required to be fully typical of a predefined class. For those resources that change continuously over Earth's surface (e.g., vegetation and soil), raster mapping using fuzzy classification usually preserves more information and better reflects human knowledge than the traditional vector mapping using crisp classification. Raster mapping using fuzzy classification not only changes the way people generate and interpret resource maps but may also change the way they represent the knowledge of the

Figure 1 Resource map: an example

Source: Author.

resources that they want to include in the maps. Specifically, with vector mapping using crisp classification, our focus would be on where to draw the boundary between two classes, whereas in raster mapping using fuzzy classification, our focus would be on what the most typical features are for a given class. The influence of this fundamental change in spatial data management on resource mapping remains to be seen.

RESOURCE TENURE

Legal tenure arrangements for natural resources such as minerals, fisheries, forest products, petroleum, among others, are fundamental to economic relationships in any human society and the cultural landscapes they create. At any geographical scale, claims to resources and systems to manage and use them must address the economic, environmental, cultural, and political dimensions of resources and the places in which they occur.

Geographically uneven distribution of natural resources is a key spatial characteristic of the environment. Social, political, and cultural responses to this spatial differentiation are fundamental to the proposition that geography continues to matter in the contemporary world, where it is often suggested that globalization foreshadows the “end of history” and the “end of geography.”

Resource geographies demonstrate that access to, control of, and identification with natural resources remain fundamental—even defining—elements in human social formations. Indeed, some political scientists suggest that social claims to and conflict over resources are central in all human politics. We can easily define politics and resources as interdependent, with various human activities at different scales involved in obtaining, using, and distributing the resources required to produce and reproduce biological, social, and economic life constituting the basis of all human politics.

In all contemporary states and environments, the economic, cultural, and legal constitution of property rights in resources and the institutionalization of these rights in systems of legal

tenure are an important facet of governance and political economy. Most societies recognize a collective claim to territory and a right, even an obligation, of the members of the collective to protect their shared interests through the exercise of exclusive rights (including a right to exclude others from their territory and the enjoyment of its resources). The boundedness of different societies varies, with modern states typically seeking strict border controls and rigid control of (some) aliens. In smaller-scale societies, the porosity of the edges of society and territory often reflects diverse environmental, social, and geographical circumstances. For example, in arid areas of Central Australia, there are competing conceptualizations of groups and resources, depending on whether environmental and economic circumstances are considered a “feast” (in which case, social strategies of inclusion and the extension of obligation are emphasized to increase the range across which people are able to secure sustenance) or a “famine” (in which case the generosity of inclusion is limited as far as possible to the closest family and kin). In modern nation-states, where the metaphor of a “level playing field” seems to propose that global trade can occur in defiance of geographical differentiation and ecological (and cultural) diversity, the edges of society and territory are often porous only to capital and privilege, with human bodies disciplined through strategies of control and exclusion.

States have created tenure systems built on claims of universality. In settler societies, preexisting indigenous systems of resource governance and the political geographies they support were largely ignored and erased—assumed to be “inferior” to European imperial systems underpinned by Christian ideologies of divine providence and the economic imperatives of accumulation. Colonial and postcolonial states established a claim of ownership over resources, sometimes allowing surface and subsurface property rights to adhere to land tenure rights, as in the United States, and elsewhere reserving resource rights to the state and allocating them separately through systems of distinctive tenures for specified resources, as in most former British colonies.

The colonial encounter historically brought quite different systems of resource tenure into

confrontation. In small-scale traditional societies, where modest technologies focused on harvest and the use of natural resources through economies based on hunting, fishing, gathering, and various sorts of husbandry of natural resources (including gardening, burning, clearing, etc.), tenure systems tend to emphasize the overlapping interests of resource managers and resource users. In other words, these societies tend to create tenure systems in which responsibility is shared in ways that reinforce the importance of social and environmental relationships and mutual obligation (including mutuality between people and their environments). One's rights and responsibilities in these systems depend not simply on "knowledge of" but also the "relationship with," "responsibility to" and "contextualized understanding of" places and their resources and characteristics. In contrast, modern property systems seek to decontextualize resources from their social and environmental settings, allowing their separation for purposes of governance, trade, and ownership. For example, separation of "water rights" from "subsurface mineral rights" and "surface property rights" creates opportunities to manage different resources for different purposes, producing the historical absurdities of overallocated river systems, where more than 100% of annual flow is "owned," as a legally enforceable property right, while market and environmental circumstances make it impractical to use water allocations productively. Examples of such circumstances can be found in arid areas of Australia, North America, and Central Asia.

Resource theorists seeking to understand the development of modern Western legal concepts of resources have suggested that the imperatives for technological innovation and wealth accumulation in industrial societies have produced specific ways of thinking about "resources" that allow this separation of certain properties of natural resources from their context—trees' functional properties as timber, for example, being separated conceptually from diverse and integrated properties contextualized as forest ecosystems.

In establishing tenure systems that entrench resource exploitation as the driver of resource management systems, industrial societies have separated the properties of specific natural

resources (timber, water, fisheries, minerals, etc.) from their geographical, ecological, and cultural contexts and relationships. In separating responsibility for management, use, and regulation, such systems vastly increase the capacity for production—as do the drivers of industrial societies' insatiable appetites for materials, land, and labor. Such separation, however, also creates the risk of vastly exceeding the ecological, cultural, or technological capacity of resource systems to recover from damage inflicted and reduces all such costs to a compensable economic surrogate rather than a geographically specific set of place-based relationships and capacities.

RESTORATION ECOLOGY

See Environmental Restoration

RESTRUCTURING

Restructuring refers to a process in which significant and rapid changes dismantle an existing structure and lead to the formation of a new one. Rooted in Marxist analysis, the concept of restructuring in the discourse of social science suggests qualitative changes in the relations between constituent parts of a capitalist economy that affect the way society is organized and operated.

The term *restructuring* is most frequently applied to dramatic economic transformation and is thus often used to mean economic restructuring. The concept of economic restructuring can be applied at different scales. On a micro scale, *restructuring* refers to a process of making a major change in the organizational structure of an enterprise to make it more profitable. This process, also known as *corporate restructuring*, often involves strategies such as reducing management levels, changing some major organizational components through divestiture and/or acquisition, altering the size of the work force, developing new models of corporate control with altered ownership structure, and redefining the firm's core activities and internal and external boundaries. These changes at the firm level result in changes in the way economic activity is organized across geographical space.

At macro levels, restructuring denotes a transition from an old economic structure to a new one with distinct spatial manifestations. On a global scale, economic restructuring (or industrial restructuring) represents the shift in industrial production from industrialized economies (i.e., the core) to the economies of the global periphery. Theories of economic restructuring have gained currency since the 1970s, when a recession, sparked by the 1973 oil crisis, hit the world capitalist economy and ended the long postwar boom. The system of the world capitalist economy responded to the crisis of the old structure through rearranging production space, a process

that Logan and Swanstrom (2005), following David Harvey, called the "territorial fix." Manufacturing jobs began to be outsourced from North America and Europe to developing countries in Asia and Latin America. Capital outflows in the form of foreign direct investment operate on a global scale, typically looking for cheap production sites. With internationalization of production spearheaded by transnational corporations and the spread of industrialization, especially in a number of rapidly growing, newly industrializing economies (NIEs), a new international division of labor emerged. At the national level, parallel to the new industrialization in other areas, advanced industrial nations have experienced a transition toward service economies in their process of deindustrialization. Since the 1990s, the new international division of labor has strengthened itself with the outsourcing boom of (low-end) services to the NIEs.

Industrial restructuring has acted as a driving force, leading to major spatial realignments at the regional and city levels. As the traditional manufacturing regions of North America and Western Europe went into apparently terminal decline and became the "Rust Belt," factories and employment relocated to low-cost, nonunionized locations with environmental amenities. The new regions of growth, such as the Southern United States (the so-called Sunbelt), were built on new industries (e.g., services, oil exploration, aerospace) and certain old industries (e.g., manufacturing, defense). This regional shift exacerbated the prevailing urban decline in cities of the Rust Belt and propelled urban growth in the Sunbelt. At the city level, urban industrial restructuring unfolded in parallel with national trends. Services began to replace manufacturing as the leading industries in urban economies. Producer services, in particular, became new engines of growth, with a concentration in major cities.

A process associated with changing the geography of industry and employment, economic restructuring represents a response to changed conditions, which may be induced by factors such as technical change, labor-capital conflicts, and the inherent competitive social relations of capitalism. The process may also be closely related to changing regimes of accumulation (i.e., from the Fordist regime of accumulation to a new regime

of flexible accumulation), accelerating circulation of capital, increasing globalization of the world economy, and (consequential) heightened competition.

Restructuring, or the process of moving from one structure to another, is often viewed as a process independent of human will that takes place according to some logics inherent to capitalism (as described above), especially the logic of capitalist competition and cost reduction. In this sense, restructuring is a spontaneous process that generates impacts at different geographical scales.

One the other hand, *restructuring* has been increasingly used to refer to a neoliberal political-economic strategy or policy agenda of the government. Thatcherism and Reaganism, for instance, represented particularly aggressive programs of neoliberal restructuring during the 1980s. State power was mobilized behind “state-authored restructuring projects” characterized by marketization and deregulation, aimed at the central institutions of Keynesian-welfarist settlements. Since the 1980s, neoliberal programs of economic restructuring have been extended globally by the G-7 to peripheral and semiperipheral states. Bretton Woods institutions such as the World Trade Organization, the World Bank, and the International Monetary Fund, which were transformed into agents of transnational neoliberalism, actively promote trade and market economy principles, as well as Western values of democracy and human rights. These institutions use their financial instruments to get countries in the Third World that face economic hardships involved in various structural adjustment and decentralization/deregulation programs. Economic restructurings in these less developed capitalist economies are more or less “responsive” (or “passive”), as they are to a large extent imposed from outside or “above.”

Poor children stand in a plot of land where a new shopping mall will be constructed in Gurgaon, Haryana, India (2005). Since 1991, economic reforms have transformed India into one of the fastest-growing economies in the world.

Source: Amit Bhargava/Corbis.

While restructuring theory originated in, and has mostly been applied to, (advanced) capitalist economies, it can be extended to other political economic settings. The abrupt transition of the former socialist countries, including the Soviet Union and Eastern European countries, to capitalism during the late 1980s represents an extreme of structural change. Parallel to capitalist restructuring, several years of *perestroika* (restructuring) in the Soviet Union during the mid 1980s, a “revolution from above,” had profound consequences. While the intended consequences included a fundamental transformation of the Soviet economic system and creation of a market economy (of a social democratic type), the unintended consequences

included the dissolution of the Soviet state and the end of the Cold War.

Less abrupt but still profound restructuring has been occurring in other socialist countries such as China and Vietnam. Unlike perestroika in the 1980s or “shock therapy” from the early 1990s in Russia and Eastern Europe, reform of the economy in China has followed a gradual approach whereby Communist Party control is maintained alongside a gradual establishment of a market economy framework. China’s three decades of economic reform have dramatically changed the nation’s economic landscape. Major structural changes include, but are not limited to, a rapid structural shift in employment activities and output, diversified ownership structures of firms and industries, a shrinking state sector in most industries, and increased foreign trade and foreign investment. Economic restructuring has its strong spatial manifestations. Alongside the structural changes of the economy, regions display changing patterns of uneven development. Meanwhile, Chinese cities are also undergoing profound transformation, with rapid suburbanization, new patterns of urban land use, a changing spatial structure, and the formation of new social and cultural spaces. Somehow inspired by China’s experiences, socialist countries such as Vietnam and, to a lesser extent, Cuba have also adopted a gradual approach toward economic reform.

Restructuring should not be restricted to the economic domain alone. The concept can refer to different processes of change, for example, structural changes in the organizational form of economic, social, and political institutions. Restructuring of capitalist economies is often driven by capital-labor relations; on the other hand, economic restructuring can also shape capital-labor dynamics and transform social relations. If left to itself, for instance, the process of restructuring may exacerbate class inequalities. As discussed earlier, restructuring often requires the involvement of the state and/or transforms state capacity. From the culture perspective, economic restructuring has been associated with postmodernity, just as it has been associated with flexible accumulation.

RETAIL TRADE, GEOGRAPHY OF

Retail trade is one of the world's largest economic sectors and is the final step in the distribution of merchandise from producers to consumers. The geography of retail trade is concerned with the spatial patterns of stores, the behaviors of consumers, and the spatial interactions between them. Research on retail trade contributes to a better understanding of economic processes. For example, retail trade can be analyzed in terms of consumer demand and its behaviors, and store supply and its strategies can be examined in the context of various geographic scales. Retail studies show that there are significant demographic differences in the retail attraction of stores, each of which has a different distance decay effect. Different socioeconomic profiles of customers have also influenced retail trade. For example, income is a good indicator of store choice. The spatial dimension of retail trade is important since every store's trade area is influenced by its location, its proximity to different types of customers, and the layout of other competitive stores.

Retail stores vary greatly in size—from small local shops to large supercenters that form part of national chains. The best way to understand retail trade is to know the customers and where they are located. Both demographic and behavioral analyses are approached in retail trade research to understand consumer behaviors. Demographic studies use basic population characteristics such as age, income, marital status, and so on. These

demographic factors often account for buying patterns. Behavioral analyses emphasize consumer attitudes, values, and perceptions; social factors that shape consumer behavior; perceptions of different stores; and attitudes toward shopping as an activity, which vary by age, income, gender, ethnicity, and location.

Retail Trade Establishments and Spatial Changes

Retailing represents sales of new and used goods in small quantities to the general public for personal or household consumption, as it is located in retail outlets without including the informal retail sector. There are three main components in store-based retailing: sales, outlets, and selling space. Retail sales represent the value added in the distribution of goods and services to consumers, excluding value-added or sales tax. Retail outlets are business units that are used principally for retail trade; therefore, each store within a shopping mall is counted separately. Retail selling space refers to floor space within a retail store used for trading; it is also known as sales floor area, trade area, trading area, sales area, and retail square footage.

Among retailers, grocers are the geographically dominant retailers, selling foods, beverages, tobacco, and other everyday household items at supercenters, supermarkets, discounters, and small grocery retailers. Supercenters are retail outlets selling groceries and nonfood merchandise with a minimum retail sales area of 26,910 ft.² (square feet). They are usually located in suburban malls or shopping centers as the anchor store that is easily accessible by automobile. Exemplary brands include Walmart, Target, Kmart, and so on. Supermarkets sell groceries with a selling space of between 4,306 and 26,910 ft.², selling at least 70% groceries. Supermarkets grew quickly across the United States with the growth of suburban development after World War II. Most North American supermarkets are located in suburban strip malls as a “draw tenant” along with other small retailers. They are generally regional rather than national in their company branding. Representative names include Kroger, Safeway, and so on. Kroger is one of the most nationally oriented supermarket chains in the United States.

Discounters sell mainly private-label or budget brands selling core, high-volume grocery products; the size is typically 3,229 to 9,688 ft.², stocking 1,000 to 4,000 product lines. Aldi and Save-a-Lot are good examples of discounters. Their relatively small size has helped discounters penetrate urban markets, where real estate is generally more expensive than in suburban locales, and also allowed the companies to carve out a niche in neighborhoods that supermarket chains neglect. Aldi, for example, has about 950 stores in 29 states and plans to open more in Connecticut, Missouri, and Texas. Unlike supercenters and supermarkets, accessibility to public transport is one of the important criteria in the location decision by discounters. Relatively speaking, they are easily accessible by foot, by bicycle, or by public transit, compared with supermarkets or supercenters.

Retail stores chased the middle class to the suburbs. The small and scattered retail stores in the suburbs were replaced by large shopping malls, which need land for the construction of their “big boxes.” Enormous parking lots built on relatively cheap land are necessary for shopping malls in the suburbs. The entry of supercenters or supermarkets affects employment patterns in the metropolitan areas, especially local retail employment. For example, Walmart employs 1.3 million people in the United States; a typical Walmart store with 100,000 ft.² employs 150 to 350 people, and a Walmart supercenter employs 400 to 500 people. Suburban growth is accompanied by regional shopping malls, which also are major creators of employment. The concentrations of employment in peripheral urban areas have created a need for retail services, and regional malls and shopping centers and have affected housing patterns.

Theories and Models of Retail Trade Location

Retail location decisions offer many opportunities for differentiation because each location is unique. Even contiguous locations may produce large differences in sales volume, sometimes for reasons that can really never be determined. Recent advances in geographic information systems (GIS) have made the retail location decision a relatively easy process. Location variables of retail trade, including population, traffic flows,

competitive locations, and related factors, are input into location models that provide detailed assessments of alternative sites. GIS continue to change the landscape of retail trade. Retailers use GIS to identify underserved regions and overlapping trade areas of influence, to compare various markets from a national perspective, and to target specific stores for relocation due to intensification of competition. Retail trade areas can be mapped with the help of census or ZIP code boundaries. Using U.S. Census data such as blocks or block groups, detailed demographic information can be studied. Linking information to location is a process that applies to many aspects of retail trade. Retail trade area analysis makes decisions regarding the types of market areas that should be serviced, the locations that should be used, the size of new facilities, and related decisions that serve as a foundation for site selection. It also analyzes demographic and competitive information, looking for cities or neighborhoods where new store potential is the highest.

The federal government’s Census of Retail Trade enumerates retail establishments in the United States. The data include number of establishments, sales, payroll, and employment and appear in reports by geographic areas, by industry, and by major retail centers. Consumer expenditure data can be obtained from the Bureau of Labor Statistics. The *Consumer Expenditures Annual Reports* are published annually at the national level and summarize various consumer demographic characteristics. Income and household information are also available for download from the U.S. Census Bureau. A customized database on retailers can be obtained from Trade Dimensions, which provides the retailer locations, sales volumes, and so on.

Early ideas in retail models used the central place theory, assuming that both customers and retailers make decisions that maximize their utilities. Concepts of the range and threshold of a good were adopted in explaining retail trade within settlements. According to the theory, different goods would have different ranges and thresholds. Others applied various forms of the gravity model: The law of retail gravitation, for example, allows analysts to draw trade area boundaries around cities using the distance between the cities and the population of each city.

A Walmart in Southern California

Source: Steven K. Martin.

According to the model, the larger a city, the larger a trade area it has. The extent of a trade area of a city is determined by the breaking point between multiple cities or centers. The model presumes that the cities are on a flat plain without any rivers, freeways, political boundaries, consumer preferences, or mountains to modify an individual's progress toward a city. A probabilistic retail model considers two components of retail attraction: (1) the store size and (2) the travel time or the distance between the consumer and the store.

Spatial interaction models—a family of gravity models—can be used to predict the flows of consumer dollars from residential areas to retail destinations. Spatial behavior in spatial interaction models is not different from that in the central place theory. With demographic characteristic inputs such as population and household income

values as well as consumer expenditure data into a spatial interaction model, it is possible to predict consumer interactions between consumers and individual retailers. Interactions are measured in terms of revenue and are correlated directly with store attractiveness and inversely with distance between consumers and retail centers. Such a model would greatly improve on the multitude of existing retail planning methods. While GIS currently support limited retail analysis functions, they are capable of supporting spatial interaction modeling through advanced data manipulation. The implications of spatial interaction modeling in retail trade would be valuable in predicting potential revenues for various site locations. There has been extensive academic research on the application of spatial interaction models to retail trade to explain how the models should work.

Retail Trade Without Distance

Internet-based retail trade rose with the Internet, which changes the geography of retail trade. The 21st century has seen a seismic move in the way in which store-based retailers have viewed their online operations. Online retailing, also known as e-commerce, is the latest form of retail trade. The growth of e-commerce is inevitable. As store sales fall, many retailers have found Internet sales as a way to reconnect with consumers. Major retailers begin to see the potential of using online retailing as a lower-cost way to explore their options in national markets. Recent retailing sectors have grown in electronic retailing and in the integration of e-commerce operations within traditional retailing strategies. One of the attractions of electronic shopping to customers is the ability to shop from home and the ability to compare prices from geographically dispersed sellers and order the most favorable combination of product, delivery, and customer service. In this context, location has been seemingly less critical. It is still arguable if the importance of location has decreased over time due to Internet technology. More and more retailers offer customers the option of shopping electronically and picking up purchases at their local stores. Internet retailing as a percentage of total retailing was 3.7% in 2007 and was expected to keep increasing in the United States. Exemplary companies adopting this trend include Barnes & Noble, Best Buy, Circuit City, JCPenney, and so on. The scope of geography of retail trade is already global in character. Firms are operating retail outlets in foreign countries and markets that are beyond domestic boundaries.

Retail trade is continuously changing and is competitive. New retail sites are founded in peripheral locations, new organizational forms of retail trade are always emerging, and e-commerce transfers locations into a virtual world. The spatial effects of the changes in retail centers, the globalization of retail trade, or the retail trade in transit areas and at junctions are topics of current retail trade research.

RILL EROSION

Rill erosion is the process by which numerous sub-parallel and randomly occurring small channels are formed on slopes by running water. Usually, if channel cross sections are smaller than 900 cm² (square centimeters; 30 cm × 30 cm), they are called *erosion rills*. If they are bigger, they are called *erosion gullies*, and the erosion process associated with them is called *gully erosion*. Between the rills, the removal of soil is done by sheet (inter-rill) erosion, dominated by raindrop splash and sheet flow. Rill erosion is the most effective sub-process of soil erosion by water, contributing up to 80% of the total (rill + interrill) soil erosion.

Rills occur when overland flow starts to become concentrated. Overland flow with sufficient kinetic energy generates a shear stress that can detach soil particles. At locations where such detachment occurs, the soil's surface is lowered slightly. Such lowered areas form preferential paths for subsequent flow and, thus, will be eroded further. This process results in small, linear concentrations of flow known as "microrills" or "traces," with a width and depth of few millimeters. If they grow further, they become erosion rills. Rill networks tend to be dendritic in form on natural soil surfaces but are constrained by the directions of

Ephemeral gully erosion and severe rill erosion wash away young corn plants from the ground as well as the topsoil and the nutrients from loess soils in this Western Iowa field.

tillage on agricultural lands. Once rills form, their migration upslope occurs by retreat of the headcuts on the steep banks at the top of the channel. The rate of retreat is controlled by the cohesiveness of the soil, the height and angle of the headwall slope, and the discharge and velocity of the flow. Downslope extension of rills is controlled by the flow and the strength of the soil.

Rills are often associated with the “midslope,” as they may become enlarged on the lower part of the slope to give way to gullies. Therefore, the usual sequence of erosion processes downslope is rill and interrill erosion followed by gully erosion.

The density of rills depends on slope steepness and length, runoff rate, soil texture and erodibility of the soil, and the presence or absence of rainfall. On highly erodible soil, where the limiting factor

of erosion is transport capacity, rills have similar size along the slope and exhibit high densities. On less erodible soil, where erosion is detachment limited, the width of rills varies along the slope, and their density is lower.

Typically, rills present no obstacle to normal tillage operation and can be easily removed.

RISK ANALYSIS AND ASSESSMENT

Risk analysis consists of risk assessment and management. Risk assessment combines laboratory and field data with mathematical models, assumptions, and judgments to estimate the likelihood and consequences of human and ecological risks. Risk management uses legal, economic, political, communication, and other social instruments to reduce risk and help those affected to recover from harmful events.

Risk Assessment

Personal, indoor, and outdoor environments contain obvious hazards such as hurricanes, earthquakes, tsunamis, oil tankers, landfills, and industrial facilities and less apparent ones such as tobacco products, alcohol, drugs, contaminated food, stairs, and slippery sidewalks. Risk assessment is a set of formal processes to estimate the likelihood of danger associated with hazards. Typically, the process is divided into four steps: (1) hazard identification, (2) dose-response assessment, (3) exposure assessment, and (4) risk characterization.

Hazard Identification

Is a substance or activity a hazard? Information comes from laboratory experiments that use bacteria, mice, rats, and other specially bred species to test biological, chemical, or physical hazards and activities for their toxicity, mutagenicity, carcinogenicity, and other undesirable effects. Data

also come from observing the consequences of human exposures. Both laboratory tests and human studies are valuable, but there are instances where they have not worked. For example, the chemical diethylstilbestrol, developed to treat morning sickness in pregnant women, had been tested in laboratory animals, yet it caused birth defects in humans. Likewise, drawing inference from human observations is hindered by confounding factors, which make it difficult to separate the effects of different hazards. For example, diesel fumes are potentially carcinogenic, but human studies have found it difficult to separate the effects of diesel fumes from tobacco smoke and other occupation exposures.

Another complication is that some studies show that a substance is a hazard, but others do not. A recent widely publicized example is electromagnetic fields created around lines that carry electrical power across the landscape. Some studies show that electromagnetic fields can cause cancer. Others, including nearly all the recent ones, show no effect. Many hazard studies are inconclusive, especially if the substance or activity is a weak hazard, or a hazard for one animal but not for another.

Dose-Response Assessment

This second stage evaluates the amount of exposure that produces a harmful effect. Dose-response assessment is essential because harmful effects are detected at high doses. Most human carcinogens, for example, were detected in a workplace where employees were exposed for many years to high doses. Animal tests in laboratories are expensive, and hence, the number of animals tested may be limited; and the doses are high and enhanced by solvents that increase the chance of producing a cancer. If a chemical, biological, or physical agent is dangerous at high exposure levels, is the same agent dangerous at a low exposure? Risk assessors look for exposure levels where a substance is not a danger or for the so-called no observed adverse effect level, or NOAEL.

Thresholds are different for every chemical, biological, and physical agent. Many heated debates have occurred over which mathematical curves statisticians should use to estimate dose and

response. For example, the human body is able to repair cell damage caused by low-level exposure to radiation, which suggests that there is a threshold that produces no effect. In fact, some scientists believe that a small dose is beneficial (hormesis), triggering the immune system into an accelerated protective mode. But hormesis, which was shown to exist for food nutrients such as selenium and some other metals, is highly debatable in the case of radiation (also, e.g., cigarette smoke). Regulatory agencies assume that there is no threshold for radiation with regard to cancer; in other words, any exposure increases the probability of cancer. This is not the case for other outcomes (e.g., birth defects), which use threshold models.

Exposure Assessment

Exposure assessment evaluates how hazards reach and injure people and the environment. Sometimes, as in the case of vehicle crashes, the exposure pathway and the cause of damage are apparent (e.g., blunt force, explosion, fire, smoke). But the vast majority of hazards impose risk by more subtle pathways—by discharging hazardous substances into the air, land, and water. The process of learning how hazardous chemical, biological, and physical, agents move through these media is called “fate and transport.” Fate and transport may be simple; for example, if a worker spills a strong pesticide or solvent and then tries to wipe up the contamination without gloves, she or he may develop a skin rash.

Exposure pathways often are complicated. A hazardous discharge can vaporize into air and later fall to Earth at a different location; it can move through soil and rock and into underground water supplies, later to be consumed by someone who relies on her or his own well for drinking water. A massive spill or chronic discharge of pesticides or solvents can flow into a river, a lake, or a local aquifer, killing fish, birds, and other species. In addition, fish, birds, and other animals can drink water polluted by the spill or eat contaminated plants and animals, thereby introducing the contamination to the food chain. Assessing complex fate and transport pathways involves using mathematical models and applying assumptions about the concentration of the hazard, the direction of the emission, and the duration and

frequency of the exposure. The results of this part of exposure assessment are estimates of how much exposure takes place in different places and times.

The next part of exposure assessment is understanding how the hazard enters the body. This is accomplished by examining its properties in the environment and determining whether the exposure will be through the skin, inhalation, ingestion, or multiple routes. Route of exposure assessments are critical because some substances are much more dangerous through one route of exposure than through others. For example, mustard gas (a chemical warfare agent) can be harmful to the skin but can be fatal if inhaled, which is why gas masks are required for individuals who may come into contact with it.

Exposure assessments examine both short-term and long-term emissions. Short-term emissions, sometimes called acute episodic emissions, assume accidents, ruptures, failures, or other unexpected events. Long-term emissions, often called chronic emissions, assume routine discharges. Because there are literally an infinite number of exposure conditions, federal agencies specify the conditions for studying the hazard concentration, the frequency and duration of their discharge, and the type of exposure. This avoids markedly different risk estimates because of different assumptions. Notably, these specifications almost always are conservative—that is, they are protective of human health by assuming relatively high concentrations of hazard, high frequency of hazard, long duration of the hazard, and exposure entry points to the hazard that are the most serious.

Risk Characterization

The final stage of risk assessment involves integrating the results of the first three steps into an overall assessment. Critical to this final step is indicating the degree of scientific confidence in the data and tools and specifying the key uncertainties. Uncertainties are caused by lack of understanding, inadequate data, small size of experimental databases, using test species that are not representative of humans, and other variable experimental conditions. Typically, risk assessments will report the most probable results and at least one reasonable worst case one. The latter is

the worst possible case, which is likely to be implausible (e.g., a person living near an incinerator stack for 70 years). Overall, a good risk assessment should contain credible estimates of the likelihood of death, injury, or other losses associated with a hazard.

Risk Management

Risk management is the process of making choices about risks. Before describing risk management, it is important to note that risk assessment, while intended to be an entirely scientific endeavor, does contain embedded management decisions. As noted above, in the absence of credible information, agencies typically require conservative protective assumptions. Risk managers also take other nonhazard factors into account—most notably, economics, ethics, public reaction, and politics.

Economics

Many people believe that we should not put a value on human life. But courts often do and society through its political processes explicitly or at least implicitly does. Every risk-related decision produces economic winners and losers. Analysts use benefit-cost, cost-effectiveness, and other economic methods to evaluate economic consequences. For example, if a hazard is likely to produce 100 additional cases of cancer over a 10-year period and it costs \$1 billion to eliminate the risk, managers will doubtless debate if spending \$10 million per cancer case is an appropriate benefit. Economic tools range from those that estimate the value of an individual life to those that estimate the regional and national economic impacts of risk-related decisions. Benefit-cost analysis is a highly developed subfield of economics and risk analysis, with much debate about the assumptions, metrics, and models of each method.

Many current risk-related policy issues involve economic considerations, raising a variety of questions such as the following: Should the United States look for oil in environmentally sensitive areas? Should a new bridge or tunnel be built between New York and New Jersey? Should the United States ship used nuclear fuel to Yucca Mountain in Nevada, or should it remain at each nuclear power plant? These policies and

many others have important economic and risk consequences.

Ethics/Morality

Right and wrong, ethical and unethical, and moral and immoral are dichotomies routinely offered about risk management decisions. For some people, drilling in the Arctic wilderness is an immoral act; for others, it is a practical response to high oil prices. Some argue that nuclear power is a Faustian bargain that future generations will have to deal with, while others believe that it is a relatively safe approach to electricity generation and a better choice than fossil fuels. Some would preclude locating hazardous, unsightly, and odorous facilities in neighborhoods if the neighborhood is disproportionately occupied by minority and economically disadvantaged populations. The principle is that poor and disadvantaged minorities should not be disproportionately burdened with locally unwanted land uses and activities. Others would rely solely on “scientific” risk and environmental analyses to determine the location—that is, no location should be precluded unless there is an undue risk. Notably, many believe that the most important change in environmental policy in the United States during the past two decades has come about because of the environmental justice movement. Projects that otherwise would have ignored the demographic composition of the surrounding population now explicitly take that into account during the design and planning stages.

Also, many observers recognize an environmental ethic, which is a set of principles that urge people to live in harmony with Earth rather than attempt to conquer it. This ethic is now considered worthy of formal inclusion in public risk management debates rather than being dismissed as an idealistic irrelevance.

Public Reaction

Public perception of hazards can affect decisions. During the 1970s, the environmental impact assessment process and events began to alert U.S. residents to the impact of potential problems with deepening rivers, building dams and bridges, oil spills, power plants, factories, hazardous waste

sites, hurricanes, earthquakes, and many other human and natural events. We have learned that the public disproportionately fears hazards that they are unfamiliar with and hazards that can have catastrophic consequences. We also know that negative information is generally remembered longer and has a much greater impact on perception than positive information. This leads to the reality that the U.S. general public and most others are more concerned about nuclear power plants and waste management sites than about cigarette smoke, alcohol abuse, and driving without a seatbelt, irrespective of scientific data that show a much greater risk from the latter than from the former.

Politics

Risk management decisions are ultimately political decisions. Formally, the U.S. government—the state and local governments pass laws—and their departments use rules and regulations to manage risk. Government leaders issue executive orders to make decisions when laws and rules are not in place. The courts are drawn into disagreements about risk management decisions.

The formal decision-making process is paralyzed by an informal one. Decision makers understand and must deal with the reactions of elected officials who may control their budgets, industry, not-for-profits, the mass media, and other interest groups that have a stake in the decision. Elected officials want to know the likely public reaction to their decisions about energy technology, transportation, waste management, and many others. Public perception may not alter political decisions, but elected officials may attempt to communicate the reasons for their decisions to the public rather than risk the public's wrath.

A Risk Analysis Dilemma: Remediating Former Nuclear Weapons Sites

One of the most challenging issues that risk analysts have addressed involves remediation of sites where the United States developed, manufactured, and tested nuclear weapons and where waste products are stored. These massive sites (hundreds of square miles in area) are Hanford (Washington), Idaho National Laboratory,

Nevada Test Site, Oak Ridge (Tennessee), Los Alamos (New Mexico), and Savannah River (South Carolina). Some of the deserts, forests, prairies, and wetlands surrounding these large sites are contaminated with radioactive materials released from the facilities.

The question is how much remediation should be done at these sites. Because these locations are so far from urban areas, risk assessments show that they pose relatively little risk to human health, except perhaps for workers who would be injured during remediation. Yet radiation and sometimes chemical exposure to the animals and plants can be a risk. Should the U.S. Department of Energy (DOE) spend billions of dollars to remove contaminated materials? The DOE's position is that remediating these sites is legally required by agreements it made with state governments and other parties.

Almost 80% of DOE land on these sites is not contaminated, a good deal of which is protected for research, preservation, or recreational use and by prohibition of public access since the sites were opened in the late 1940s or early 1950s. Some of these DOE lands are the ecological jewels of these regions.

If the DOE remediates the contaminated land to remove any residual human and ecological radiological and chemical hazards, it is likely to cause irreparable damage to these ecosystems. Contamination can be reduced by removing the soil. This also requires roads to carry the contaminated soil to a resting place, which is almost surely going to be on the same site. Such remediation, many risk analysts believe, will likely injure animal and plant populations more than the existing radiation. The remediation will destroy intact ecosystems that will not recover because of the degree of soil or other loss. Remediation could be so harmful, for example, that it would destroy the indigenous seed bank and allow external invasive species to move in, eliminating native species. Also, the disruption will cause animals and other species to move out of the area and into adjacent inhabited areas in order to escape remediation. The risks imposed by some of the legacy radioactive elements will slowly decrease if there is no new contaminant release, because radioactive substances decay over time. (For some, with long half-lives, there will be no appreciable decrease for centuries.)

Finally, remediation has the potential to reintroduce presently controlled contaminants into the environment because of the disruption and exposure of plants, soils, sediments, and underground and surface water supplies. For ecosystems, the best approach is to leave the contaminants where they are, except where there are clear risks because of a radiological or chemical hot spot. If necessary, remediation should be done with as few new roads and other disruptions as possible. In short, the greatest risk to an ecosystem is from the actual physical disruption that destroys the ecosystems themselves rather than the residual radiation and chemical contamination. The dilemma is that the federal government is required by legal agreement to remediate these sites. The risk analysis suggests reconsideration.

Conclusion

Risk assessment and management are not new ideas. Every day, each of us takes small, medium, and sometimes big risks. Many of us eat foods that raise our cholesterol, are outside when lightning strikes, smoke cigarettes, and in other ways engage in activities that increase our risks. Most people are willing to take risks that they control and assume voluntarily. A good skier believes that she or he controls a downhill run and assumes the risk of injury because she or he enjoys skiing. For others, the idea of strapping on sticks and going down a steep hill at 6 a.m. is an unacceptable risk.

From a society perspective, new products and activities are being created, and old products and activities are reaching new customers, placing more people at risk. Our ability to detect hazards has dramatically increased during the past two decades, and so when there is a hazard in the environment, we are more likely to know about it. And we are more likely to care about it because the deadly risks of a century ago that kept the average lifespan below 60 years largely have been controlled, allowing more focus on a new set of hazards. We need risk assessment and management to provide information to decision makers who are the stewards of our limited resources to protect public health and environment. Risk analysis is not a panacea for decision makers, but it has helped them make better decisions.

Geographers have been involved at all levels of risk analysis process. Many work on risks and environmental assessments for the government and private organizations. Others have become leaders in the Society of Risk Analysis, a multidisciplinary international organization.

RITTER, CARL (1779–1859)

One of the great intellectual giants of 19th-century geography, Carl Ritter was an influential professor in Frankfurt and Berlin. He is often described as one of the two principal founders of

modern geography, compared with his contemporary, Alexander von Humboldt.

Son of a doctor, Ritter became from 1798 to 1814 a tutor for the children of Bethmann Hollweg, a wealthy local banker who financed his university education. In school, he studied botany, art, theology, philosophy, and history, and he taught himself Greek and Latin. His first geographical publication appeared in 1804, and by 1816, he had acquired a reputation as a geographer. After a year as professor of history in Frankfurt, he moved to the University of Berlin as a professor of geography, occupying the first German university chair in that discipline. He became deeply interested in Africa and was a militant abolitionist and opponent of racism. He became a member of the Prussian Academy of Sciences, and in 1828, he founded the Berlin Geographical Society. His early works included textbooks about the geography of Europe.

Ritter, who did not travel much and never outside Europe, is most well-known for his massive 19-volume magnum opus, *Die Erdkunde im Verhältniss zur Natur und zur Geschichte des Menschen* [*The Science of the Earth in Relation to Nature and the History of Humanity*], consisting of more than 20,000 pages, which he wrote between 1817 and 1859 (and never completed). It concerns only Africa and Asia and dwells on the relations between humans and the biophysical environment. The work became enormously successful and helped move geography beyond the study of maps to include the various ways in which people responded to the world's varying climates and ecologies.

Ritter viewed the world's regions through the conceptual lens of religious teleology, seeing in the world's geography evidence of divine purpose. The Earth, he held consistently, was designed by God for people and could only meaningfully be viewed in this way. In this respect, he differed greatly from the more secular and scientific Humboldt. Ritter's focus lay primarily on human geography rather than the natural environment. He attempted an ambitious comparison and synthesis of enormous amounts of data through a regional approach at a continental level, contrasting the Northern and Southern Hemispheres as well as the New World and the Old World. Geography's purpose, he held, was to detect the whole character of places—to

identify unity within diversity. Disdaining simple lists of facts, Ritter advocated comparative local studies through which broader generalizations could be made. However, his approach was purely inductive, and he distrusted deduction as a matter of principle; in this respect, his ideas resembled the chorology of Richard Hartshorne, who, not surprisingly, admired Ritter greatly. His view tended toward an organic theory of the state, which was becoming popular in emerging geopolitical conceptions of the world.

Ritter was a highly popular teacher. His students included Élisée Reclus and Arnold Guyot, and he heavily influenced Friedrich Ratzel and Alfred Hettner. He died in 1859, the same year as von Humboldt.

RIVERS

A river is a physical landform that conducts (primarily fresh) water, sediment, and nutrients downslope under gravity from topographically higher land toward depressions at a lower elevation, most often into bodies of water. The total volume of water in the global hydrosphere that can be found in rivers is miniscule (0.0001%), yet rivers are a key part of the hydrologic cycle, conducting water delivered to the landscape via precipitation, springs (groundwater), or glacial meltwater to oceanic environments. The river channel, or depression of varying width and depth, contains water at least sporadically, if not constantly, depending on its geography. A river's physical character is a direct result of its local

climatic and geologic conditions, which may vary with distance along its course. As both erosional and depositional agents, rivers are highly dynamic and adjust their forms over time as a response to the active processes that influence them. Rivers are recognized as one of the most influential physical forces on Earth, each year reworking about 19 trillion tons of suspended and dissolved solids. Rivers are responsible for shaping a majority of continental and coastal landscape features and provide unique ecosystem environments that foster the development of biological diversity rivaling that of both rain forests and oceans.

Most rivers across the globe have been diverted, dammed, or drained as a result of human activity. Rivers are also a hazard to the global population, with floods destroying human infrastructure and taking thousands of lives each year. With the effects of global climate change beginning to unfold, rivers are responding in concert. Flow regimes are changing to reflect both human influences and climatic shifts. Changes in flow cause geomorphic responses such as aggradation or degradation of the channel bed, reduced interactions between the river and its floodplain, and altered floral and faunal cues that affect the health of riparian ecosystems. This entry outlines the fundamentals of river science, including river geography, the impact of geology and climate on rivers, drainage networks within watersheds, and river processes and the resulting landforms (fluvial geomorphology). It then examines both the impacts of rivers on humans and the impacts of humans on rivers.

River Geography

Rivers can be found on every continent and in every climatic region. Variations in their latitude, altitude, and physiography combine to create characteristics unique to each system. Within each drainage basin, a river's makeup will change as it flows through varying topography, geology, and climate; thus, a river's headwaters will likely bear no resemblance to its mouth. The surface area of land that a river drains is called a drainage, or catchment basin. These land areas, also termed *watersheds*, are divided by rises in topography at their outer boundaries. As a river grows in size via the addition of tributaries to the

network, so does its drainage area. The largest rivers drain continental interiors and create depositional landforms, called deltas, at their mouths. Deltas are accumulations of sediment that over time form specific patterns depending on their sediment supply and the local oceanic currents.

The largest river on Earth in total length is the Nile (Africa), while the largest in total discharge is the Amazon. The Amazon is also the longest river in South America. Globally, the longest rivers on each continent are the Mississippi (North America), the Yangtze (Asia), the Darling (Australia), the Onyx (Antarctica), and the Volga (Europe).

River Formation Variables: Geology and Climate

A river's physical expression is the result of in situ landscape conditions and its response to local climatic events. Geology and climate are two defining factors in the geomorphology of a river.

Geology determines slope of the channel and sediment size and distribution; floodplain size and shape; and the groundwater/surface water relationship. As a river flows through its drainage basin, the local geology may change, and as a result, the physical characteristics of the stream adjust as well.

Climate provides the amount of water delivered to the channel via overland flow processes and is a major factor in determining the volume of flow. A river is formed when the subsurface is saturated to such a degree that no greater amount of water can be absorbed, and thus, the water begins to run across the surface. Rivers are categorized by the frequency of water presence in their channels: Perennial channels contain water virtually year-round, ephemeral channels contain water only periodically (mainly after a precipitation event), while intermittent channels are climatically driven and, typically, flow only during wet seasons.

Drainage Networks

Drainage networks are formed when streams of increasing size converge and form a pattern. River nomenclature is not universally defined, where the terms *stream* and *river* are often used interchangeably. Typically, a stream is smaller in

The Amazon River flowing through the Amazon rain forest. The Amazon is also the longest river in South America.

width, depth, and discharge than a river, but not always. Rivers create drainage patterns that are identifiable from above. These patterns are typically referred to as a river's planform, or planimetric geometry, and take on distinct shapes depending primarily on their underlying geology. Drainage networks can be categorized as dendritic, radial, trellis, or rectangular.

As a stream network begins to form, it drains the landscape in the most efficient way; hillslopes converge and dissect the land in a branching pattern; hence, the root of the word is from the Greek *dendro*, for "tree." Dendritic networks are the most common type and are scale independent. They are self-similar in nature, meaning that regardless of the scale of observation (stream size)

the drainage pattern when viewed from above does not change. Other drainage patterns are more geologically controlled, as the underlying rock structure plays a dominant role in the surficial expression of the stream network. A radial drainage pattern is typically found in an environment where a landform feature creates a cone-shaped structure, like a volcano, and the resulting drainage pattern looks very much like the spokes of a wheel. Trellis drainage is common in mountainous areas where ridge and valley geology dominates, and the rivers create a network of flow that parallels the mountain's ridges. Rectangular networks are structurally controlled by the underlying bedrock. Streams follow faults or bedding planes in the rock beneath the surface, as

these are areas of weakness that steer flow directionality and cause the rivers to make abrupt changes in flow direction (sometimes 90° turns) that are only possible in natural environments under such conditions.

River Processes and Forms

Processes

Dynamic Equilibrium

A river's energy and physical matter are in a state of constant flux. Rivers seek balance between dependent (sediment load and discharge) and independent (climate and geology) variables. Termed *equilibrium*, this self-regulation is the catalyst for river form adjustment. When one variable changes, the river adjusts and will continue to do so until it again reaches a stable form. For example, below a dam a river will attempt to balance its reduced sediment load and modified downstream discharge regime by entraining sediment and thus degrading the channel bed.

Flow Mechanics and Regime Factors

Channel cross-sectional area is determined by measuring the channel's width and depth at a particular location along its reach. A river's cross-sectional area, however, is not descriptive enough to determine the characteristics of the channel. Two rivers of vastly different widths and depths can have the same cross-sectional area. The amount of friction that water creates at the river's bed and banks, instead, is a function of its cross-sectional shape and is represented by a width-depth ratio. Channel bed and bank configuration determines the amount of available energy, called velocity, and the amount of friction generated at the riverbed by the volume of water above it. Velocity, or the rate at which water flows at a particular point in time at a specific location along its course, is directly related to the width-depth ratio: Bed and bank contact creates frictional drag and slows water, and thus, velocities are greatest where this frictional drag is least. Water velocity is directly related to several factors, including the channel gradient (slope), channel size and shape, bed and bank roughness, and discharge.

Discharge is the amount of water that is flowing in a river at a given place and time and is measured as a volumetric rate (cubic feet per second or cubic meters per second). The amount of discharge is calculated at a particular place and time by multiplying the channel cross-sectional area (channel width by channel depth) by the water velocity. Discharge is directly proportional to the size of the watershed upstream that is being drained. As watersheds increase in size in the downstream direction, so does the river width, depth, velocity, and discharge. River discharge varies with distance along its course, fluctuating both diurnally and seasonally, and is highly responsive to localized precipitation events; snowmelt in mountainous regions sends volumes of frothing water and sediment downstream each spring, while regional climatic events, such as monsoons, can cause massive flooding in low-lying areas.

A river's flow regime can be described through the following metrics: frequency, duration, timing, magnitude, and rate of change of flow. Determining a stream flow rate is achieved by measuring the stage or discharge at a particular location on a stream, at a given time. In 1889, the U.S. Geological Survey established the first stream-gauging station on the Rio Grande River to measure the daily stream discharge. The program blossomed into a national network, which in 2007 included about 7,500 stations, with more than 150 million "at-a-station" daily discharge values recorded since the program's inception. Due to the massive volume of data over an extended time period, this resource is invaluable for completing change detection in the hydrologic regimes of rivers. The number of stream-gauging stations has fluctuated throughout the past century, depending on national need or budgetary conditions. Now, other nations throughout the globe have begun concerted efforts to gauge rivers and create data sets useful for determining long-term trends and the effects of global climate change.

River science reveals the complex relationships between system variables. A river's suspended sediment load, width, depth, and velocity are all directly related to its discharge. As a river network increases in size in the downstream direction, its stream order increases, as does the number of streams, the mean stream length, and the mean drainage area.

Sediment Transport and Deposition

A river's slope and velocity determines how much sediment it can pick up and entrain (carry) downstream. Sediment in transport is called a load and can be subdivided into three categories:

1. Dissolved load is sediment in solution.
2. Suspended load is sediment carried in the water column.
3. Bed load is the sediment that saltates or skips along the bottom of the channel.

Dissolved load is most often introduced via groundwater contributions to river flow, where the rocks that it flows through leach minerals into the water. Suspended load has been picked up and carried downstream after enough friction has been generated at the riverbed to do so: Entrainment depends on the material type and the river velocity as clay particles are easily transported once entrained and only settle in placid environments, while sand particles are more easily entrained but settle more quickly as velocities are reduced.

Forms

Bed and Bank Configurations

River forms are the physical result of local geomorphic processes at work. Bed, bank, and channel pattern adjustments occur in response to system disturbance. Bed and bank configurations are unique to the volume of discharge and sediment generated by the upstream watershed, riparian vegetation, material composition, and channel slope. Due to these dynamic factors involved in river formation, river beds almost always undulate and are rarely flat. As a result of varying velocities on the bed and banks, different forms result. The primary material composition that makes up the bed also plays a defining role in channel characteristics; bedrock, silt clay, sand, gravel, and boulder beds generate considerably different fluvial geomorphologies.

Channel Slope and the Longitudinal Profile

A river flows downslope from its headwaters to its mouth and terminates at either a lake or an

ocean (baselevel). Gradient is usually steepest at the headwaters and flattens out with river distance. Elevation change that occurs along its entire course can be graphically represented in a longitudinal profile and typically follows a concave-shaped curve.

Channel Patterns

Horizontal adjustments counteract changes in the longitudinal direction and cause specific channel patterns. Planimetric geometry is the result of several forces at work on the channel: sediment size and sediment load (bed and bank erodibility) and channel slope and river discharge (stream power). In nature, a straight channel is an anomaly. Straight channels are most often the result of structural (geologic) controls over a short distance or channel engineering by humans. Thousands of miles of naturally meandering rivers have been straightened and channelized for navigation or other purposes.

Because the determinants of channel pattern are directly related to continuously changing variables in the longitudinal direction, selecting a pattern for a particular channel reach must be done on a continuum, where the threshold separating meandering and braided channel patterns may vary with system geography. Rivers tend to initiate migration from side to side within their floodplain as a function of in situ flow and sediment interactions. These migrations, called meanders, vary in their number and geometry depending on the river system of study. Sinuosity, or the amount of meandering within a defined river distance, is calculated by dividing channel length by straight-line valley length. Meandering channels are most common in nature. When a river meanders, water velocity and erosive power are focused toward the outside of the meander bend, creating cut banks and causing the meanders to migrate downstream and change shape over time. On the inside of the meander bends, velocity is reduced and sediment settles to create in-channel forms such as midchannel bars and point bars.

Braided channels occur in environments where sediment load exceeds the river's carrying capacity. Braided rivers have many subchannels that are interwoven between unvegetated bars of sediment that are constantly being mobilized and redistributed. Braided rivers are most commonly

found in environments where there are easily eroded channel banks, excessive bed loads, highly variable discharge, and steep valley slopes, such as in glacial outwash plains.

Impacts of Rivers on Humans

Humans have used rivers for public water supplies, food sources, waste disposal, energy creation for mechanization and electricity, and recreational and aesthetic opportunities; as modes of travel and transportation; and as accesses for military conquests and barriers for defense. Rivers provide religious, social, and economic benefits and also have political roles, serving as borders between all levels of political jurisdiction. Rivers, through human modification and the development of irrigation systems, have allowed for settlement in arid environments previously unsuitable for habitation. For example, the fertile crescent of the Tigris and the Euphrates rivers in modern-day Iraq is deemed the birthplace of civilization, made possible only through the presence of these important rivers. Egypt's Nile River also provided an oasis for human habitation, with its seasonal flooding delivering vital nutrients to the farmed floodplains, allowing for the rise of one of the most advanced societies in human history. Despite these widespread benefits, rivers also pose a hazard for human populations that live within their floodplains. Floods caused by climatic events or dam failure have the potential to cause catastrophic damage to human-made infrastructure and to take countless human lives.

Impacts of Humans on Rivers

Humans have been modifying rivers since prehistoric times. In modern times, humans have had significant impacts on river systems, where in countless cases such as the Los Angeles River of California in the United States, the channel no longer resembles a river but a storm water conduit. In many watersheds, such as the Los Angeles example, water diversion from the river channel along its course results in a complete dewatering in its lower reaches. Most damaging has been the widespread effects of dams. River regimes are substantially different from natural flows. Flooding

is suppressed from downstream environments, and floral and faunal species can no longer depend on seasonal flooding events to act as reproductive cues. Sediment now stored behind dams fails to reach river mouths, build deltas, and nourish beaches. Dams block fish passage to spawning grounds and have led to the deterioration of entire species and the economies they support, such as the salmon industry of the Pacific Northwest in the United States.

Pollution generated by human activities has also been detrimental to riverine environments. Many rivers in the developing world act as a means for waste disposal, and untreated human waste and garbage flows freely to oceans. In the past four decades, the developed world has begun to pass laws to protect rivers from these activities. The Clean Water Act of 1972 began to regulate point and nonpoint source pollution in the United States from the perspective of discharges to rivers. The negotiation of international water laws is in its infancy, however, and will become increasingly necessary in the future due to the shared nature of river resources between nations and the pressure placed on them due to increasing populations and the effects of global climate change.

ROCK WEATHERING

Weathering is the in situ alteration, by disintegration or decomposition, of rocks and minerals. By weathering, rocks and minerals reach a new equilibrium (chemical, pressure, and/or thermal) with the surface environment. Disintegration refers to the in situ mechanical production of smaller particles without chemical change, while decomposition refers to chemical alteration that results in both smaller particles as well as dissolved ions. Mechanical and chemical weathering are convenient subdivisions for discussion, though it is understood that the mechanical and chemical weathering processes are symbiotic and often inseparable.

Weathering is of vital importance to numerous Earth systems (and is therefore a subject for transdisciplinary study). Weathering is one of several geomorphic processes, as weathering alone or in conjunction with other geomorphic processes is responsible for creating and modifying landforms. In petrology, weathering is a key function of the rock cycle, in which all the major rock types exposed on Earth's surface are ultimately vulnerable to weathering. Sediments, and sedimentary rock, could not exist without weathering first, and weathering is a primary means of recycling Earth materials. Soil is another feature that directly depends on weathering, as the mineral proportion of soil derives entirely from weathering by-products. Last, and of recent scientific attention, weathering is seen as an important function of biogeochemical cycles, as weathering is one of the true interfaces between all of Earth's

geosystems (land, water, air, and life). Weathering plays a role in liberating or sequestering elements and in transferring these elements between biota, air, and water.

Types of Weathering

Mechanical Weathering

Mechanical weathering involves physical forces (compressive, tensile, and shear) that cause rocks and minerals to fracture (i.e., exceed the limit of plastic deformation). A number of physical forces are present in terrestrial environments.

Cryostatic pressure involves the compressive stress due to the expansion of water ice. Sometimes referred to in many writings as "frost" weathering, the process is not limited to the presence of frost crystals. Water ice is unique in its tendency to expand on the change of state from liquid to solid. Typically, liquid water works into the voids of existing rock weaknesses such as cracks, sutures, bedding, voids, or mineral or grain boundaries. In the confined spaces of the rock weakness, ice crystal growth exerts considerable pressure, forcing the rock or mineral apart. As the rock weakness void grows, confined pressures decrease, and the ability to continue cryostatic weathering decreases. Intense or prolonged stress will eventually completely separate the fragments. The products of cryostatic weathering are angular rock fragments, frequently observed in alpine, subarctic, and arctic regions.

Cryostatic pressures can be emphasized in environments with diurnal freeze-thaw cycles, in which ice crystal growth, melting, and regrowth allow repeated physical force. Freeze-thaw cycles are expected in temperate or midlatitude climates, though in polar areas rock surfaces exposed to sunlight can reach above-freezing temperatures even in winter. Cryostatic weathering is suspected on Mars in locations where water is or has been present.

Like ice, *expansion and growth of other crystals* in confined spaces also exerts compressive pressure to cause or enlarge fractures. Iron minerals, calcite, and expansive clays are examples of crystal growth weathering. However, salt (any of the alkaline minerals, including NaCl) is the chief and most common example cited and observed. Salt can enter the

A tor, near Crow Creek, southeastern Wyoming. Existing joints are widened by mechanical weathering such as ice, while chemical weathering results in disintegration and rounding. Lichens growing on much of the rock surface enhance chemical weathering. Erosion of weathered material leaves the spectacular remnant boulders.

Source: Courtesy of Jeffrey Pope.

rock or mineral by way of solution in water. As water evaporates, the salt is left behind and will expand as it crystallizes. Similar to ice, salt weathering will produce angular shards of by-product rock. Salt weathering is prevalent in arid and semiarid climates, where rapid evaporation is more apt to leave salt precipitates within the surface rocks rather than flushed by solution into deeper soil or groundwater. Salt weathering may be prevalent in polar

deserts, where lack of liquid precipitation allows salts to accumulate at or near the surface. Thus, what is often assumed to be ice weathering may in fact be attributed to salt. Salt weathering is also seen in coastal areas, where sprays from waves can move inland up to several kilometers by way of atmospheric transport. Stone conservationists have noted salt weathering on building stones. Salt sources in urban areas include atmospheric aerosols, streets and sidewalks, and mortars.

Hydrostatic pressure is exerted by thin water films in small pores and fractures. Almost always present even in dry environments, hydrostatic pressure may be responsible for prying apart microfractures in rock. Water microfilms can exist in the presence of subfreezing temperatures, such that liquid water may in fact be responsible for some of the weathering attributed to ice.

Rapid or extreme temperature changes are believed to create variations in the volume of rocks or minerals themselves. Rock expansion due to heating and rock contraction due to cooling may therefore exert compressive and tensile forces, respectively. There is some debate as to how much plastic deformation a rock will tolerate before fracture, thus a debate about how important temperature changes can be toward weathering. Still, most experts would agree that temperature changes have at least some impact. The critical factor pertains to diurnal temperature change. Diurnal ranges of 40 °C per day are not uncommon in deserts, while surface changes of 20 °C per hour are possible in temperate

continental climates. *Thermal* weathering is a term applied to environments of extreme heat, for instance, on dark rocks in tropical deserts or in proximity to fires. *Cryogenic* weathering pertains to environments of extreme cold.

Pressure unloading involves a volume adjustment of rocks formerly under considerable mass and pressure. Most rocks (apart from surface-cemented or solidified volcanic rock) are produced

deep in the crust under immense pressures. When erosion exposes these rocks to the surface, the atmosphere exerts pressure at $\sim 1/1,000,000$ th that of the crustal interior. Rock will then expand somewhat plastically to a point where a brittle fracture occurs. Unloading fractures tend to occur just below the rock surface and parallel or concentric to the surface. Slabs of rock millimeters to meters in thickness spall off (often aided by gravity and water). Landforms resulting from pressure unloading often appear dome shaped (e.g., Half Dome in Yosemite, Sugarloaf in Rio de Janeiro), with “onion” layers of slabs yet to fall.

Biomechanical processes of plant roots and animals are specialized weathering agents. A common image of tree roots attached to rock crevasses suggests the tenacity of plants and their ability to fragment rock. In reality, roots take advantage of preexisting fissures, and the physical pressure of root growth has been shown to be negligible except in soft and fragile rocks. Fine roots are known to expand and contract due to variable moisture content, and this may be a factor in mechanical weathering at smaller scales. Most likely, the very active chemical environment of roots contributes a synergistic weathering environment.

There are a few instances of weathering by animals. A species of desert-dwelling snails consume endolithic lichens and, in so doing, also consume parts of the rock substrate at appreciable rates. Species of bivalve mollusks are known to bore small holes into rock by a combination of chemical excretions and physical consumption of the mineral material. Other rock- and soil-dwelling animals (earthworms, insects, etc.) may similarly attack rocks by a combination of mechanical or chemical means, though the subject is poorly researched.

Chemical Weathering

Chemical weathering involves the decomposition of rocks and minerals at the elemental or molecular level by means of chemical reaction with exogenic weathering agents. Rather than attacking structural weaknesses as mechanical weathering does, chemical agents attack weak molecular bonds, removing elements to solution, consequently weakening the mineral and rock

fabric. Chemical weathering therefore removes material in the form of ions and promotes further decomposition of rock by means of granular disintegration (between crystals or particles).

Solution, or congruent dissolution, is the simplest form of chemical weathering. It involves water in the complete solution of the mineral into aqueous ions without precipitation of secondary minerals in the solution process. Water is all that is necessary for solution weathering, though acids and organic chelates can greatly enhance the solution potential. Calcium carbonate (calcite), calcium sulfate (gypsum), and silica (quartz) are examples of minerals that are subject to solution weathering. Of these, quartz is the least soluble by several orders of magnitude—a testament to its resistance, though not permanence, in the terrestrial environment.

Hydrolysis or incongruent dissolution is sometimes referred to as complexing, and rightly so. The complete process takes place in several steps with intermediate by-products and precipitates. Hydrolysis refers to the H^+ ion available in aqueous acids, carbonic acid being common in the terrestrial environment by way of naturally acidic rain, though organic acids are also important in soils and surface water, and sulfuric acid can be present near hydrothermal areas and in the presence of old mines (“acid mine drainage”). Polluted air in industrial and urban areas may contain both sulfuric and nitric acids, and acid precipitation may drift by prevailing winds into pristine regions. The weathering of aluminosilicate minerals (such as feldspars and micas), the most common in Earth’s crust, is most apt to be from hydrolysis. The process yields dissolved cations (such as potassium, sodium, and calcium), silicic acid, silica precipitates, and clay minerals (such as kaolinite, illite, and smectite). High-resolution electron microscopy of minerals attacked by acid reveal incipient molecule-sized etch pits, while more extensive weathering results in a skeletal lattice of remnant mineral (see photomicrograph image). An ultimate residual of aluminosilicate hydrolysis is aluminum oxide, Al_2O_3 , a stable mineral known as bauxite that is highly resistant to further weathering. Both bauxite and kaolinite are valuable economic minerals, the former for aluminum metal and the latter for a variety of ceramic, paper, and medicinal materials.

Source: Photomicrograph courtesy of Dr. Ronald Dorn, Arizona State University.

Hydration is a relatively simple absorption of water molecules into the mineral, which disrupts the crystalline structure (and creates a new mineral). Hydration causes an increase in volume and mechanical pressure. Hydrated micas are partially responsible for granular disintegration of coarse-grained igneous and metamorphic rocks. Hydrated shrink-swell clays achieve similar stresses. Amorphous glass (e.g., silica glazes and obsidian) can also hydrate and decompose. *Dehydration* is the removal of water molecules under hyperaridity or high temperatures (such as extreme wildfires). Dehydration leads to a collapse of the mineral structure and a decrease in volume.

Oxidation is a chemical process by which mineral ions are lost due to the introduction of an oxygen ion in the presence of water. Iron is the most common subject of oxidation, and iron-bearing minerals such as the amphiboles, pyroxenes, olivine, and biotite are vulnerable. Removal of Fe^{2+} (ferrous iron) combines with the oxygen

ion to form Fe^{3+} (ferric iron), a much less soluble ion that precipitates easily. Resultant by-products of the reaction include hydrous and oxidized minerals of iron such as hematite, limonite, and goethite. Rocks containing iron-bearing minerals first exhibit reddish or brown halos around the minerals, while more complete oxidation can tint the entire rock (see rock weathering photo). Oxidized iron-rich cements account for the red color in many sandstones, and iron mineral residua is responsible for rubification in soils.

Chelation is a complex chemical process by which metallic ions are selectively removed in the presence of organic substances. Large organic acid molecules (such as ethylene diamine tetraacetic acid [EDTA] and amino acids) are examples of chelating agents and, unlike hydrolysis reactions, attach to the metallic ions through numerous (rather than single) bonds. Chelates, by way of decomposed organic material or within the roots of plants, aid in the release of nutrients to plants. Lichens are thought to have strong chelating agents, one factor that allows these pioneering symbiotic plants to use bare rock for sustenance. Lichens are responsible for the creation of incipient soils and soluble ions in environments that are lacking in other chemical weathering agents.

The Geography of Weathering and Weathering Factors

The extent and intensity of rock weathering is moderated by a number of factors (Figure 1). Many of these factors are highly geographic in nature; hence, weathering has a real variability from small to large scales.

Time, Scale, and the Geomorphic System

Weathering is among the slowest of geomorphic processes; considerable time elapses before significant modifications to the landscape occurs. Weathering over a given time produces a weathering rate. Rates of weathering vary considerably due to the availability of weathering agents, nature of the parent material, and environmental parameters, most relevant at small scales. Weathering is generally not a straight-line and constant process over time but more usually a decaying

Figure 1 Relationships of environmental and microscale factors relevant to the weathering system

Source: Author.

rate over time until reaching an equilibrium state, consistent with any chemical and physical reaction. There are some instances where weathering rates may increase over shorter durations of time—for instance, when dissolution opens up greater surface area to attack, resulting in more and faster weathering. However, this also reaches an eventual equilibrium. Weathering rates are most likely to be polycyclic and metastable, not unlike most geomorphic systems.

Weathering rates are well studied around the world as they give an indication of landscape evolution and environmental change. In some cases, weathering rates are so well established that they can reliably indicate elapsed time and hence can be used as a relative and occasionally calibrated numeric dating method. Examples of these applications include the width of stone weathering rinds (see granitic stone photo), the diameter of tafoni and rock basins, and the proportional abundance of less weatherable minerals in sediments and soils. Most often, significant geomorphic modification is a synergistic combination of weathering with other geomorphic processes (the

Source: Author.

combined process referred to as *denudation*). Erosion is capable of exerting larger landscape modifications when preconditioned by weathering, in which weathering weakens and softens the rock prior to erosion. Landscapes are sometimes referred to as “weathering limited,” meaning that the efficacy of erosion and transport is held back by slower rates of weathering, or “transport limited,” in which weathering is aggressive but erosion is not capable of keeping pace by removing

the weathered material. Weathering and transport limits are frequently cited in support of tectonic and climatic models for landscape evolution, though relief, lithology, vegetation, and land use are equally relevant.

Landscapes dominated by weathering processes (but helped by other geomorphic processes) are some of the most dramatic on Earth. Examples include the deep regoliths of the Brazilian shield; the tower karst of Guilin, China; and remnant tors and inselbergs in Dartmoor (England), East Africa, and Australia. In mountainous landscapes, the work of weathering is less recognizable but still highly significant. Owing to the increased exposure of fresh, unaltered rock, new mountain ranges promote rapid weathering and the addition of a heavy solute load to the surrounding streams and rivers. Studies in the Rocky Mountains and Scandinavia attest to high levels of chemical weathering despite cooler temperatures. A recent (though contested) theory suggests that very active orogeny in the late Cenozoic Era (e.g., Himalayas) allowed increased chemical weathering and profligated an atmospheric drawdown of carbon dioxide, perhaps decreasing the greenhouse effect enough to trigger climate change.

At smaller scales, weathering at focused points and with aggressive agents can cause significant modification over shorter time periods. These myriad small-scale landforms reflect a diversity of interacting processes, type localities, and odd names—for instance, *gnammas* (rock basins), *tafoni* (honeycomb-like hollows), *karren* (solution channels), and *hoodoos* (rock pinnacles). Small-scale weathering forms are the product of differential weathering and erosion and sometimes exhibit process positive feedback as well as self-organized geometry (see tafoni photo).

Not limited to the natural environment, small-scale weathering is also a matter of concern in the case of buildings, and the processes and mitigation of damage in them are an important focus of research.

Petrology, Mineralogy, and Geologic Structure

Weathering is easiest and proceeds fastest along rock and mineral weaknesses, these weaknesses being the product of rock and mineral formation and crustal stresses. Rock and mineral weakness is a factor across scales, from submicrometers to many kilometers. Minerals have a range in resistance to weathering owing to both crystal structure and composition. This attribute translates up in scale to the composition of the rock and to lithologic differences.

Fractures present avenues of weakness as well as paths of contact with weathering agents. Fractures are present at the smallest scales, within mineral grains. At the largest scales, networks of fractures (including fault zones) allow fluids to penetrate and create greater surface area. Quarries are ideally situated in rock outcrops relatively devoid of fractures, minimizing the chances for weathering and easing the ability to remove large intact slabs of workable stone.

Over larger scales, the variation in lithology (by composition or structure) would factor into variations in weathering and erosion rates, resulting in differential landscapes of landforms resistant to positive relief and less resistant to negative relief. Resistant landforms (such as bornhardts, inselbergs, buttes, tors) have been described as having a more resistant composition compared with the surrounding rock, fewer fractures, or both.

Colorado National Monument, Colorado. Weathering away of the protective caprock of the overlying Kayenta Formation has produced rounded tops on all but the left-hand shaft, which is still protected by the Kayenta.

Source of Weathering Agents, Climate and Biotic Influences

The abundance and efficacy of weathering agents is a factor in the geography of weathering (Figure 1). Concentration of weathering agents will yield faster weathering rates and more intense weathering. Because of the ubiquity of water in almost all terrestrial environments (possible exceptions in hyperarid deserts, though the

persistence of this condition over weathering timescales is debatable), chemical weathering is nearly always available. At least one type of mechanical weathering is present in terrestrial environments. Again, variation of weathering agents is evident at changing scales. For example, at regional scales, increased precipitation, perhaps aided by enhanced levels of atmospheric acid, may account for increased chemical weathering (evident in increased solute load in streams). Certain biomes would be more conducive to increased levels of organic acid (e.g., pine barrens or sphagnum bogs). Certain climate regions are more favorable for mechanical weathering (e.g., due to freeze-thaw cycles or salt). Variations in weathering agents at centimeter-to-meter scale account for differential weathering. Individual plants (e.g., lichens, trees) can locally enhance the chemical weathering environment. Microclimatic difference can influence temperatures and the availability of water and organisms. Small-scale declivities in the land or rock walls can concentrate weathering agents as well as influence the microenvironment. In contrast, small-scale armor-ing (rinds, rock coatings) protects rock from weathering by retarding the access of chemical agents or indurating the rock against mechanical stresses. Finally, the efficacy of weathering agents can decline over time as the material evolves from higher to lower weathering potential.

ROSE, GILLIAN (1962–)

Gillian Rose has long encouraged geographers to contemplate the gendered construction of geographical knowledge. Her research ranges from analyzing the cultural politics of landscape to exploring notions of the performative and visual methodologies. She is perhaps best known for her 1993 book, *Feminism and Geography*. Through an explicit critique of geography's masculinist leanings, Rose reveals that geographers have constructed geography in ways that legitimize masculine forms of geographical knowledge at the expense of feminist ones. Rose has also intervened in key debates about feminist geographical methodologies, drawing on insights from Judith Butler to critique assumptions in feminists' use of reflexivity as a way to construct geographical knowledges. Referring to the ways in which gendered sameness and difference are constituted through geographical traditions, in "Tradition and Paternity" Rose (1995c) emphasizes that "given th[e] persistent erasure of women, the construction of geographical traditions might . . . be described as the construction of geography's paternal lines of descent" (p. 414). She insists that

feminists . . . need to critique the transparent territorialization of tradition . . . we need to focus on the boundaries at which difference is constituted . . . this project entails thinking about geography through a different spatiality: a multiple space. (p. 416)

Rose draws on feminist discourses on the maternal body, or woman as mother, to subvert masculinist structures of knowledge in geography. Her work has been strongly influenced by psychoanalysis, and this has largely shaped her understanding and theorization of space. The sophistication of Rose's arguments, especially her continual

questioning of the epistemology and ontology of the discipline, suggests that the notion of an “explicit sexualisation of knowledges” (Grosz, 1993, p. 188) must be taken seriously by geographers.

Rose’s 2001 book, *Visual Methodologies*, examines methods in visual culture approaches, from discourse analysis techniques to the study of audiences. Drawing on her interest in psychoanalytical theory, Rose argues that sexual difference is articulated through visual practice. This book offers a comprehensive study in methods to examine visual culture, from discourse analysis techniques to the study of audiences. Examining how we interpret images and how these processes are laden with power and cultural meaning, Rose provides a critical visual methodology, where she examines the visual in terms of cultural significance, social practices, and complex power relations. Drawing again on her understanding of psychoanalytical theory, Rose persuasively discusses the ways in which sexual difference is articulated through visual practice. Rose’s argument about critical visual methodologies has already been effectively extended into the arena of geographic information system imaging and has proven an important contribution in geography and representation.

Rose’s work in the late 2000s began to examine the ways in which visibility is experienced in urban environments, contributing to a sensuously embedded geography of vision. In developing a new urban aesthetics, Rose insists on the importance of a self-reflexive understanding of the researchers’ position on fieldwork, thus echoing a similar but not identical commitment toward reflexivity as her work in the 1990s demonstrated. Her 2009 article “Who Cares for Which Dead and How?” draws on the notion of necropolitics as a theoretical jumping-off point for the analysis of the British press coverage of the 2005 London bombing. Rose shows that newspaper coverage of the attacks was gendered and racialized, forcing the reader to consider the complex relationship between caring, necropolitics, and its accompanying visualities and spatialities.

ROYAL GEOGRAPHICAL SOCIETY

The Royal Geographical Society (RGS; with the Institute of British Geographers [IBG]) is the United Kingdom’s (UK) learned and professional society for geography and geographers. It is a dynamic institution, with a distinguished history and a powerful modern reputation and brand. Founded in 1830, the RGS-IBG is the largest geographical

society in Europe and one of the largest and most active in the world. It operates at the international, national, and regional levels from its London-based headquarters and nine regional branches.

The society's purpose remains the same today as when it was first founded—namely, the “advancement of geographical science” (enshrined in its Royal Charter in 1859). However, the manner in which this goal has been pursued has expanded greatly over the years. Today, the society is involved in a broad and integrated program of activities supporting geographical research, from education and outdoor learning, to public engagement and knowledge transfer, to policy making. As well as supporting and helping develop geography, the society actively promotes, advises on, and represents the discipline to a wide range of stakeholders. It is governed by a board of trustees, a council, elected from its fellowship.

The history of the society for many of its earlier years was closely allied with colonial exploration in Africa, the Indian subcontinent, the polar regions, and Central Asia, especially associated with names of explorers such as Livingstone, Stanley, Scott, Shackleton, Hunt, and Hillary. The society's collections are an unrivalled repository of this history, with more than 2 million items tracing 500 yrs. (years) of geographical discovery and research that continue to the present day. Included are more than 1 million maps and atlases, 500,000 images (photographs, sketches, art works, and films), and books, reports, and manuscripts. Recent initiatives have focused on “unlocking these archives”—that is, opening public access and adding educational value. Reinterpretations by community groups are at the core of the current Crossing Continents project and associated exhibitions, for example.

The society has devoted much attention to education and was responsible for both the incorporation of the study of geography in schools at the turn of the 20th century and the first university positions in the discipline. With the advent of a more systematic study of geography, the IBG was formed in 1933 by some society fellows as a sister body to the society. RGS and IBG coexisted for 60 yrs. until they merged in January 1995 to create the RGS (with the IBG).

Today, the society continues to influence educational discussion and debates both in schools and

higher education—the director serves in an advisory role to government—and is integrally involved in developing benchmark statements for the discipline and advocates for the position and funding of the discipline in schools and universities. The society established the case for further support for geography teaching at school in discussions with government between 2004 and 2006. As a result, since 2006 the RGS-IBG has been a lead partner, with the Geographical Association, in the Action Plan for Geography. This 5-yr. initiative, funded by the U.K. government, aims to inspire and support school teachers in their task to inform, engage, and enthuse young people with geography. In addition, through Geography Outdoors, the focus of much of the society's work with young people remains on fieldwork, exploration, and discovery, engaging youth from many backgrounds in the United Kingdom and overseas.

In terms of advancing geographical research, the society publishes three leading, international academic journals—*Transactions of the Institute of British Geographers*, *Area*, and *The Geographical Journal* (currently in its 175th volume)—and the RGS-IBG book series of scholarly monographs. It supports 27 research groups; organizes an annual conference attended by more than 1,200 international scholars; runs more than 20 different grant programs for geographical research, fieldwork, and teaching in the United Kingdom and overseas, supporting hundreds of geographers at different career stages; and is the hub for information, networking, and support for departments across the United Kingdom. The society is an active contributor to IGU (the International Geographical Union) and the EUGEO (a society of scholarly geographical societies, associations of geographers, and other membership organizations representing geographers and geographical sciences in the European Union countries).

Broader initiatives to promote the wider understanding, relevance, and enjoyment of geography are supported by a rich program of public lectures (including the flagship “Monday night lectures”), discussions and debates, online resources, and publication of the popular *Geographical Magazine*. The society also leads the promotion of the recognition and understanding of the relevance of geography

and geographical information to policy, placing geography firmly in the debates about the future of places, environments, and communities. This work is advanced through policy-briefing papers, proactive media work, and events providing a forum for dialogue between government, parliamentarians, researchers, NGOs, and business.

The society recognizes, through its medals and awards, geographers who have contributed to the advancement of the discipline—the most prestigious of which are the gold medals. Recipients include William Morris Davis (1919), Sir Halford Mackinder (1945), L. Dudley Stamp (1949), Richard Chorley (1987), David Harvey (1995), Nicholas Shackleton (2005), and Derek Gregory (2006).

Since 2002, the society has been granted the power to award the status of Chartered Geographer—a professional accreditation for those applying their geographical knowledge, understanding, and skills in the workplace. The society also warmly welcomes those who wish to join as fellows and members in the United Kingdom and across the world.

For details about the society and its activities, and references to papers and books on the RGS-IBG, see the Web site www.rgs.org.

RURAL DEVELOPMENT

Rural development is the practical and intellectual effort to improve the economic welfare of people living in rural areas.

History of the Concept

The conceptualization of rural development is closely associated with the emergence of the “rural” as a social and geographical category in the early 20th century. In the beginning, such development was closely linked to a nascent rural geography, and until the 1960s, it was difficult to differentiate between the two. Practitioners constructed the rural as an abstract space that could be manipulated to stimulate development (typically framed through the discourse of “modernization”) in areas where demographics indicated a dispersed population and extensive land use. Issues, staffs, and programs were organized largely along the sectoral lines of state bureaucracies such that rural development itself became a highly fragmented enterprise involving multiple agencies concerned with agriculture, labor management, entrepreneurship and small business, environment and resources, and social services.

The 1970s saw the rise of an “integrated” approach to rural development premised on the coordination of the environmental, economic, technological, and policy aspects of agricultural production. Beginning in the 1980s, rural development experienced a marked shift in conceptualization and implementation as scholars and practitioners alike began to retheorize the concept of rurality itself. In practical terms, this led to an increased focus on cultivating local human and natural capital in rural communities through participatory and collaborative initiatives that featured the direct involvement of multiple groups of stakeholders. Collectively, these new, regenerative approaches are referred to as “endogenous” development. Contemporary rural development approaches such as these have emerged in a political-economic climate characterized by state devolution of environmental and social management authority to local communities and organizations.

Central Questions

The history of rural development, and by extension its various approaches and schools of thought, can be interpreted as responses to a pair of fundamental questions.

Who or What Is Rural?

First, who or what is rural? The forerunner of modern, government-led rural development can be found in policies and conceptualizations related to the “frontier” zones of state expansion and settlement during the 19th century. Over the following decades and on into the 20th century, state governments were instrumental in promulgating a modernist approach to development that defined rural space as an area distinct from the urban-industrial cores of economic and political activity. In the context of so-called modernization, development consisted largely of “top-down” efforts focused on issues unique to rural space—the dominance of primary sector activities (i.e., forestry, agriculture, fishing, and mining), the entrepreneurial work culture, and small-scale production. State intervention was central in this regard as it often involved the construction of significant infrastructure (e.g., dams, roads, towns) to attract the external investment needed for modernist transformation. The 1933 Tennessee Valley Authority project in the United States and the 1949 Industrial Development Authority in Ireland are exemplary in this regard.

Modernist development was often coupled with a “growth pole” strategy, whereby urban centers in the region provided jobs and services for an entire hinterland region, while rural areas offered the necessary human and natural resources. This spatial arrangement proved problematic, however, in that it failed to adequately address the rural-urban (and local-global) linkages as well as socioeconomic change more generally, if for no other reason than that rural areas evolved in tandem with the processes of urbanization and suburbanization. Some critics questioned whether the development effects promised by rural modernization ever did in fact “trickle down” from growth centers to hinterlands.

More recently, development scholars and practitioners have answered the question of what constitutes the “rural” by emphasizing the fluidity and malleability of the concept. Instead of seeing the rural as a distinct geographical area, newer approaches favor a conceptualization of the rural as *discourse*. The result is that now many different and more diverse areas, communities, and stakeholders can effectively be considered within

the scope of a rural development paradigm. The rural is increasingly being seen less as an inert space to be managed and more as an actively constituted set of identities and practices that by necessity involve myriad actors and processes working at local, regional, national, and global scales.

In terms of development practice, new definitions of rurality have found expression in the European Union’s LEADER (*liason entre actions de développement de l’économie rurale* [links between actions for development of rural economy]) program, small-town regeneration initiatives, burgeoning farmers’ markets, community forestry, and local visioning activities. Critics of “bottom-up” approaches to rural development contend that as the state offloads development authority to local communities, the result is inefficiency in the planning and implementation process as well as an increasingly uneven geography of regeneration and deterioration across rural space as some communities are more successful than others in achieving development goals.

On What Should Rural Development Focus?

Second, what is the appropriate focus for rural development? As states expanded through colonization and resettlement in the 19th century, rural policy was largely concerned with the acquisition, distribution, and management of *land* through the coordination of preemption and sale of public property. Twentieth-century industrialization and the concomitant consolidation of state power across national space added the *commodity*—particularly the agricultural commodity—to rural development discourse. Policy thus came to focus on managing and in many cases subsidizing the production and distribution of agricultural goods, services, and labor. It was in this context that rural development came to be organized along sectoral lines, which had the effect of dividing rural communities by occupation and interest groups while simultaneously serving to stabilize rural space, both by discouraging endogenous protest and change and by fragmenting prospective political resistance and mobilization.

In the last quarter of the 20th century, intense rural restructuring undermined the twin priorities

Chinese villagers work at the construction site for a new bridge in China's rural Danzhai County, Guizhou Province (2006). The "No. 1 Document" of the year points out that with the nation in an era of insufficient grain production, expanding urban-rural disparity, and soaring national fiscal income, China's main priority is in revitalizing the countryside, as reported by the Xinhua News Agency. (The first document issued by the central committee of the Communist Party of China and the State Council each year is called "the No. 1 Central Document.")

Source: Reinhard Krause/Reuters/Corbis.

of land and commodity in development discourse. Generally speaking, states are now less interested in supporting rural capitalism as fiscal problems have mounted from decades of subsidies and as governments are increasingly pursuing neoliberal economic strategies in both domestic and foreign policy. In addition, rural communities have become more diverse as decades of outmigration have depleted the primary sector population and new residents and stakeholders increasingly promote alternative, nonindustrial uses and meanings for rural space.

Development policies have evolved in this situation of flagging state support and diversifying rural constituencies. In terms of an appropriate development focus, the net effect has been to place (certain types of) *people* at the center of the rural question, with the consequence that development has taken on an increasingly collaborative, participatory, and even place-based character in both conceptualization and practice. Indeed, some contemporary practitioners have equated rural development with local development, while others have preferred to conceptualize it in terms

of the place-based management of land, resources, and communities.

Measurement and Assessment

Changes in the measurement and assessment of rural development mirror the broader political-economic transformations outlined above. When concerned solely with land and commodities, rural development was conceived of as a state intervention designed to maximize production, stimulate external investment, and minimize input costs for firms and workers. A successful development program, then, was characterized by higher yields, incomes, and capital investments coupled with an increasingly favorable cost-benefit structure that could, in turn, justify government expenditures on social services such as health care, education, and unemployment insurance.

As rural development increasingly concerned itself with people, however, assessment has become much more complicated. While conventional economic measures are still used, scholars and policymakers are increasingly favoring alternative benchmarks that include the level of civic engagement in development projects, the enhancement of the targeted area's social and natural capital, and the overall effect of a development program on "social sustainability" (loosely defined as a community's level of cultural tolerance and commitment to its own long-term viability). Similarly, development efforts can be gauged by observing their capacity to empower traditionally marginalized groups such as women and indigenous peoples.

Connections to Social Theory

The theoretical basis for rural development has shifted over time as programs and initiatives experienced shortcomings, limitations, and even failure and as economic restructuring created new problems and opportunities for development practitioners. Social Darwinism found expression in the 19th- and early-20th-century development efforts concerned with state expansion and drew from the idea that community fitness was linked to land acquisition and modification, known discursively as "improvement." In this context, the state undertook rural development as a central

part of its own project to consolidate and legitimize control over nonmetropolitan space.

In the early 20th century, the Great Depression and postwar reconstruction infused development policy with socialist and Keynesian ideas concerning the role of the state in protecting minimum standards of social welfare in rural areas. A number of postwar welfare states emerged that actively managed labor and natural resources in rural areas for external (domestic and foreign) investment, mostly in primary sector activities such as hydroelectricity and aluminum production, agriculture, forestry, and mining. Actual development work on the ground was largely implemented and assessed within an empiricist framework in which the efficacy of rural policy could be measured and monitored using conventional economic indicators of production yields and levels of income, unemployment, education, and consumption.

In the 1970s, systems theory ushered in an "integrated" approach to rural development that sought to transcend the sectoral barriers created by the earlier welfare paradigm. Despite some success, this approach has been criticized for failing to account for the social and geographic variation associated with the different contexts in which such development was attempted.

In recent decades, the rise of the neoliberal state coincided with an explosion of theoretical work in rural studies drawing from cultural studies, structuralism, political ecology, and a variety of poststructuralist literatures. While rural development theory is now more diverse than ever before, it is generally concerned with the discursive nature of rural development praxis and the central role of social power in the constitution, implementation, and measurement of development itself.

Contemporary Research

An informal 2008 survey of leading geography and rural studies journals reveals the breadth and scope of contemporary research in rural development. Research continues in the areas of model and program construction and assessment, representing continuity in a longstanding line of inquiry in the field. Particularly notable in this regard is the introduction of actor network theory in the 1990s to understand and model the development

process and, still more recently, the elaboration of cooperative capitalism as an alternative model for endogenous programs grounded in local-global networks. Current thematic work also concerns social organizing, civic engagement, and participation; the role of development in empowering historically marginalized groups; the effects of development on local and regional power structures; and the political ecologies of development programs and initiatives, particularly in the developing world.

Parallel to these trends is ethnographic and historical work on local resistance to and accommodation of development, both imposed and endogenous, largely in the form of case studies that analyze the complex social and environmental consequences of implementing particular programs, initiatives, and projects. Case study research, for instance, has examined local protests against hydroelectric and flood control dams, government land use regulations, state schemes to relocate people and communities for industry or infrastructure, and the state's attempt more generally to attract external investment to resource-rich hinterland areas.

Concurrently and related to this case study work, another thread in contemporary literature on rural development focuses on the application of social theory to critique the assumptions and contradictions inherent in the project of development itself. Central to this critical effort is work in political ecology, discourse analysis, cultural materialism, and feminism.

RURAL GEOGRAPHY

Rural geography is the study of place-based economies and cultures characterized by (a) low settlement densities, low levels of connectivity, and hence a certain degree of isolation; (b) livelihoods that are predominantly agricultural or organized around other forms of direct dependence on natural resources and landscapes; and (c) attachments to long-standing traditions that often make them emblematic of cultural differences. Geographic meanings of the rural have been approached through contrasting urban and rural places within specific national contexts as well as across the international realm.

While urban geography is usually viewed as constituting a well-defined subfield, rural geography has often been a less visible subdisciplinary endeavor, though agricultural development has been a key topic within the broader rubric of economic geography. The prominence of urban geography, however, should also be linked to the predominance of urban populations within advanced economies, especially North America and Western Europe. In less developed contexts, especially South and southeast Asia, a majority of the population continues to be directly linked to agriculture, highlighting the significance of rural geography for an understanding of global diversities. More recently, rural issues have come to the fore across developed and less developed contexts, partly due to increased conflicts over natural resources. Within the United States, the

urban-rural divide has become a new site of conflict due to increased migration of urban populations into rural areas as part of the processes of exurban growth.

Major themes in rural geography can be distinguished into broadly economic, cultural, and political categories, even as these aspects of rural places cannot be strictly separated from one another. The first step in understanding rural places, however, has to be in terms of clarifying the meanings of and approaches to the rural.

Understanding the Rural

The idea of the “rural” usually refers to physical arrangements (low-density, dispersed settlement patterns), agriculture and agriculture-related activities (which could also encompass other forms of direct dependence on nature), and cultural distinctiveness (relatively homogeneous communities usually resistant to rapid change). It has also been argued, however, that instead of speaking of the specific characteristics of exclusively rural places, it might be more useful to focus on the rural-urban continuum, or even on the ways in which urban and rural spaces merge into one another rather than being strictly separated. A recent focus, for instance, has been on urban agriculture and the ways in which it marks the presence of what is usually associated with the rural within developed urban contexts. As opposed to this view, rural landscapes have also been key to symbolizing a unique regional or national identity, which heightens the significance of associating a clearly defined meaning with rural places. This notion is a feature of the rural that is likely to increase in value given contemporary concerns over the loss of cultural differences due to globalization.

Within the broader disciplinary framework, rural geography can be considered part of the regional approach to geography, which focuses on partitioning space into distinctive units. Thus, whereas the systematic approach concentrates on the distribution of one specific element across space, the regional approach is attentive to the combination of characteristics that constitute specific subdivisions of space and render them internally homogeneous as well as distinguish them from their surroundings. Rural geography also

has the potential to be located within a newly formulated environmental geography, which seeks to study places as both natural and social and, thus, seeks more overtly to bridge the divide between human and physical geography.

Rural Economies

Rural geography has focused on forms of agricultural operations, which vary from small-scale subsistence farming among peasant populations to large agribusiness corporations usually headquartered in more developed economies. Rural livelihoods are also connected to natural resource economies, including forestry, mining, and dam building. While such extractive industries are often associated with economic development, their consequences in terms of pollution and degradation have also devastated rural landscapes.

Rural agricultural landscapes vary from the mixed cropping patterns of small-scale farms (in South and southeast Asia) to the more homogeneous landscapes of industrial agriculture (classically represented by the American Midwest). In less developed contexts, farm fragmentation, usually due to systems of inheritance, has been a concern in terms of the viability of peasant livelihoods. More recently, the increasing role of technological inputs—including high-yielding seeds, fertilizers and pesticides, mechanization of farm activities, and access to irrigation—has led to shifts from subsistence to market-led production, this shift being more feasible for farmers with large landholdings. This technological shift in agriculture, designated as the Green Revolution, while credited with increasing food production, has thus also been criticized for exacerbating inequalities within rural contexts. In the case of more developed economies, the independent family farm has declined within the agricultural sector, which is now mostly controlled by large-scale corporations. Industrial forms of agriculture are reflected here through monocropping that requires intensified dependence on chemicals.

In the context of globalization, connections between urban and rural places are being discussed in terms of the increasing reach of commodity chains, so that urban consumers in high-income countries are now directly connected to rural producers in low-income contexts through

the medium of multinationals. The distance between sites of production and sites of consumption also means that urban areas no longer draw solely from their surrounding rural hinterlands. Thus, traditional land use models (e.g., von Thünen's model of agricultural land use) have to be modified to be more attentive to the role of global demand and competition in shaping local rural livelihoods. This becomes a matter of concern when the tastes of urban consumers in advanced economies serve to tie rural communities in less developed contexts to the uncertainties of global demand, in the process destroying local adaptations to the environment. In the context of the United States, coffee commodity chains have been examined to outline such repercussions of global commodity chains on local communities.

The isolation of rural places has always been a concern in terms of state-level planning as service delivery, including both education and health services, has been less easily spread into rural communities. More recently, however, the isolation of rural places has made them important locations for otherwise undesirable land uses, including prisons within the United States or polluting industries and waste within less developed contexts. Rural economies are also becoming part of ecotourist initiatives—as in Western Europe—through notions of heritage associated with rural lifestyles. The focus of rural economic geography has shifted in such contexts from the production of crops or animals to the consumption of scenery or landscapes. The consumption of rural landscapes is also reflected in the rise of residential developments within rural areas in the United States; these developments are often being promoted as a means to access a “rural quality of life.” The continuing decline of agriculture in the United States is reflected in these forms of exurban growth.

Rural Cultures

Rural people are widely considered to represent the more traditional aspects of culture, linked to older ways of interacting with the environment through agriculture or hunting, and more old-fashioned forms of attachments to place-based communities. Rural places are thus likely to be viewed as isolated from more mainstream,

cosmopolitan forms of culture. While this may be less and less true, given the rise of global connections, whether through extended commodity chains or the influx of new residents as well as tourists into rural areas, it is probably accurate to argue that rural areas are less open to the diverse forms of social interactions that are available in urban contexts, in part because rural places have lower densities of transportation networks.

Migration is one way in which rural places remain connected to a wider world, both in terms of the rural depopulation that has characterized demographic development in advanced economies as well as in the streams of rural-to-urban migration that are key to expanding economic opportunities for rural populations in less developed contexts. A number of studies have documented such rural migrations, and the focus has now expanded to include rural-to-urban migration across international realms. An especially productive area of study in terms of the migration of rural populations has been the gendered consequences of such migrations, whether through the experiences of women who are left behind by male migrants or the ways in which women and men differentially experience access to new economic and social opportunities through migration.

The meanings of gender in rural contexts have also been approached in terms of the division of agricultural work, with specific tasks often being designated as either male or female and valued differently as a consequence. In fact, the appellation “farmer” is itself redolent with gendered meanings, as it is usually understood to designate a masculine identity, which renders women farmers invisible within rural landscapes as well as devalues women's contributions to farming. More recently, the marginalization of different social identities within rural contexts has been increasingly highlighted to argue that rural societies are neither homogeneous nor immune to the kinds of cultural struggles, over the presence of immigrants or the expressions of sexualities, that characterize mainstream society.

Rural Politics

In terms of national politics, urban and rural populations are usually considered to be separate constituencies, and electoral campaigns are often

Harvesting on an Amish farm in Lancaster County, Pennsylvania

sensitive to these differences. While wholly rural-based political parties are relatively rare in the current context, specific agricultural interests are often sufficiently organized to matter in terms of national electoral campaigns. Within advanced economies, the politics of rural places are often cast as uniformly conservative in terms of both social and economic issues. In less developed contexts, however, where rural populations sometimes constitute a significant part of the population, rural interests have often served to establish populist, or even progressive, political parties in power.

Across developed and less developed contexts, rural communities have also become the site of struggles over meanings of conservation, as areas set aside for environmental protection often directly impinge on rural livelihoods, including dependence on hunting and forest products. Given that conservation areas in Africa, Latin America, and Asia are often geared toward Western tourists, such struggles have also brought global inequalities in the consumption of nature to the fore. The role of rural people within environmental struggles, however, should be viewed as divergent

across developed and less developed contexts, with rural people often being part of environmentalist agendas in less developed contexts even as they are viewed as opposed to environmental preservation policies in more developed places.

The recent neoliberal turn in global policy toward privatization of resources means that rural places have become key to questioning the inequalities that constitute globalization. Thus, rural, indigenous communities in Latin America, Africa, and Asia have become the site of social movements against forcible appropriation of land without adequate compensation. This has also exposed collusions between states and multinational interests. The rise of China and India has also brought rural-urban differences to the fore in terms of both the economic and the political losses experienced by rural places due to the withdrawal of the state and the increasing value of rural people as low-wage labor in new economies.

Contemporary forms of agriculture have also led to activism around two kinds of environmental concerns—related to notions of quality and community. In terms of quality, organic food movements have focused on the problems posed

by industrial agriculture to the integrity of natural and animal environments as well as the health of human bodies. In the context of community, local food movements have focused on the possible decline of rural places as they become economically disconnected from nearby urban markets. Such concerns can be considered as part of a larger turn toward environmentalism, especially in advanced economies, but they have also been raised by activists with less developed contexts as they criticize the loss of local traditions of farming due to the increasing industrialization and commercialization of agriculture. Concerns with quality and community, however, have also been criticized for privileging the needs of urban consumers over those of rural producers in both developed and less developed contexts.

Future Directions in Rural Geography

Rural geography is significant to understanding the contemporary world as rural products remain a crucial component of global flows, rural landscapes increasingly figure in elite consumption practices, and dispossession associated with natural resources extraction continues to prominently affect rural communities. Rural geography can thus be said to exemplify the contradictions of globalization: as rural places show how isolation is no longer a possibility, even as they also draw attention to the local attachments that continue to matter and often get magnified for some rural communities. The notion of spatial justice, which highlights the need to be attentive to place-based inequalities, can also be fruitfully followed on the basis of urban-rural contrasts, especially since rural geographies provide a framework for the inclusion of a large part of the population of Asia and Africa. Rural places also contribute to new understandings of the interconnections between nature and society—for instance, due to the genetic engineering of seeds and livestock and the controversial diversion of crops toward energy supply through the production of biofuels. Thus, even as it is widely predicted that the world will be more urbanized in the future, such claims need to be tempered by the continuing presence and significance of rural places in the current global economy.

RURAL-URBAN MIGRATION

Rural-urban migration is both a socioeconomic phenomenon and a spatial process involving the movement of people from rural areas into cities, either permanently or semipermanently. At present, it occurs mainly in developing countries as they undergo rapid urbanization. Job opportunities created by industrialization attract the surplus rural labor to the cities to seek higher salaries through employment in the industrial sector. Rural-urban migration is widely considered an inevitable component of the development process, though it has a broad range of consequences and implications.

Theoretical Frameworks

The main theoretical bases to understanding rural-urban migration include neoclassical economic theories and the household strategy approach.

Neoclassical Theories

The Harris-Todaro model and the Lewis dual sector model are two of the representative neoclassical economic theories illustrating the dynamics of rural-urban migration.

The Harris-Todaro model argues that rural-urban migration is mostly an economic decision

based on expected income differentials between rural and urban areas. Individuals or households make a cost-benefit calculation by comparing the expected earnings in the cities with the prevailing wages in the rural areas, and if the former exceeds the latter, migration will take place. Therefore, rural-urban migration will continue as long as the expected urban real income at the margin surpasses real agricultural returns. Migration can be seen as an equilibrating force that equates rural and urban expected incomes in the long run.

According to the Lewis dual sector model, migration occurs between the traditional agricultural sector and the modern industrial sector. The rural agricultural sector is characterized by low productivity, low wages, and excess labor, whereas the industrial sector in cities is defined by higher productivity, higher wage rates, and more job opportunities. Due to the wage differential between the agricultural and manufacturing sectors, the rural surplus labor will tend to transfer from the agricultural to the manufacturing sector over time to garner higher monetary reward. Eventually, the agricultural wage will rival the manufacturing wage, and the agricultural marginal product of labor will keep pace with the manufacturing marginal product of labor.

Household Strategy Approach

In the household strategy approach, rural-urban migration is a strategy adopted by households to maximize and diversify their earnings and minimize their risks against market failures as well as natural catastrophes. Net family gain, rather than net personal gain, encourages migration. The decision is rarely an individual one. It is usually made collectively by immediate and extended family members. Split households may take place as a result of adopting this strategy. Sometimes the husband pursues migrant work in the city and the wife stays behind to take care of the family as well as hold on to the land. During the busy season in agriculture or when family needs become urgent, migrant(s) may return temporarily to help. The remittances that migrants send back help pay the living and agricultural expenses and alleviate poverty in the household. The reason for split migration may be that the

family would want to reduce risk as well as migration cost, which can be expensive. It also allows migrants to straddle and benefit from both the rural segment and the urban segment. When migrants settle down in cities and achieve economic success and stability, family migration may occur, which means that the rest of the family members will join the migrants in the cities.

Demographics

Empirical studies have shown that the majority of migrants to cities are young and have a higher education attainment than those who do not move. They migrate because they have higher prospects of earnings and are more likely to be employed in the urban areas. It is also observed that men are more likely to migrate from rural to urban areas than women in areas where the status of women is lower, such as in most countries of Africa and Asia. Connected to the increased status of women, rural women are slightly more likely to move than their male counterparts in the countries of Latin America and the Caribbean, although most are following their husbands or family members.

Due to lack of access and the fewer skills they possess compared with the urban population, rural migrants are usually channeled into the urban informal or secondary sector. The jobs they take tend to be labor intensive, physically demanding, and low in pay. Typical jobs include manufacturing work, construction work, and domestic service. Migrants may have to face poor working conditions as well as living conditions in cities. Many of them cluster in the urban slums and shanty areas and have very limited access to basic services. Since a lot of migrants only take migration as a temporary means to increase income for the household and take the rural residence as their permanent home, they put up with the terrible living conditions in cities and maximize their savings.

Impacts of Rural-Urban Migration

Rural-urban migration has multifaceted consequences on the sending and receiving areas. The impacts are believed to be both beneficial and detrimental. From an economic perspective, migration plays a positive role in raising cash earnings, diversifying income sources, increasing the level of

A migrant worker in Beijing sorts through a mound of plastic bags at a recycling center for industrial and household waste. During 2005 alone, China's household waste reached 150 million tons, mostly collected and disposed of by migrant workers. According to China's National Bureau of Statistics, the rural migrant worker population in 2008 was more than 130 million. Rural Chinese provide the nation's cities with a workforce that is heavily represented in the manufacturing, construction, and social service industries.

Source: Michael Reynolds/EPA/Corbis.

productivity, and reducing unemployment/underemployment and poverty in the rural areas. In many developing countries, the flows of remittances are vital to the livelihoods of the family members left behind by the temporary migrants in rural areas. On a national scale, rural-urban migration helps narrow the gap between the urban and rural societies, given the distortion of opportunities in favor of cities in most developing countries. Socially, migration contributes to the empowerment of women by providing them with opportunities to work outside the home and earn income.

On the other hand, researchers believe that rapid rural-urban migration can cause excessive urbanization in developing countries, which may result

in serious issues. First, rural-urban migration contributes to unemployment and underemployment in the urban areas, which can be observed by the large numbers of unemployed or underemployed young people in many Asian, African, and Latin American cities. Second, rapid and massive population growth in cities puts extra pressure on urban infrastructure such as housing, transportation, sewage systems, clean drinking water, and other amenities. Finally, excessive urbanization causes city congestion, higher crime rates, disorder in urban management, pollution, and urban environmental degradation.

RUSSIAN GEOGRAPHICAL SOCIETY

Founded in 1845, the Russian Geographical Society (RGS) is the oldest geographical society in Russia. Headquartered in St. Petersburg, the society has gone through a series of name changes in its history, reflective of changes in Russian/Soviet history. It was known as the Russian Geographical Society from its founding in 1845 until 1849, again from 1917 to 1925, and from 1993 up to the present. It has also been known at various times as the Imperial Russian Geographical Society, the Russian State Geographical Society, the RSFSR (Russian Soviet Federated Socialist Republic) State Geographical Society, the All-Union Geographical Society, and the USSR (Union of Soviet Socialist Republics) Geographic Society.

The RGS was founded in the same era as the other great national geographical societies (such as those begun in London, Paris, Berlin, and New York). The organization's charter outlined its mission: "to gather, process, and spread in

Russia geographical, ethnographic, and statistical information in general and concerning Russia in particular, and to disseminate trustworthy information about Russia in other countries." In the 19th century, the society's main mission was to fund and sponsor expeditions "exploring" lands controlled by Russia, with an emphasis on the Asiatic portions of the Russian Empire to the east (especially Eastern Siberia and Central Asia). This eastward exploration was an integral component of the rise of Russian nationalism, with this eastward focus and attention by Russian nationalists serving as a counterweight to their growing negative views toward Western Europe.

As with many other national geographic societies, the Russian Geographical Society's emphasis today has shifted from exploration to more academic and applied pursuits. Today, the RGS is one of nearly 30 scientific organizations associated with the Russian Academy of Sciences (the RGS has had formal ties with the academy since 1938). Research interests of RGS members today span the breadth of human, physical, and regional geography and geographic techniques, with an emphasis on studying the challenges facing modern Russia from Kaliningrad to the Russian Far East. The organization's 13th Congress, held in August 2005, was attended by approximately 400 members.

SATELLITES AND GEOGRAPHY

The world's network of satellites and earth stations constitute a critical, and often overlooked, element in the global telecommunications infrastructure. While most treatments of this topic typically depict it in technologically deterministic, apolitical terms, satellites are deeply embedded in terrestrial political relations.

Satellites in orbit appear in a variety of sizes and degrees of technological sophistication. Large satellites capable of handling international traffic sit 35,700 km (22,300 miles) high in geostationary orbits, which are by far the most valuable orbital slots because only in that narrow sliver of space do satellites and Earth travel at the same speed relative to each other, making the satellite a stable target for signals transmitted upward from earth stations. Because such orbital arcs are a scarce resource, their distribution is strictly controlled through international organizations. The cost of launching satellites and the fuel needed to maintain them in their proper orbit are also constraints to their economic viability. Satellites typically have a 10-yr. (year) life span, primarily because they exhaust their available fuel, necessitating their eventual replacement by a new, frequently much improved, generation. From its vantage point, a broad-beam geostationary satellite can transmit to (i.e., leave a "footprint" over) roughly 40% of Earth's surface, creating instantaneous time-space convergence, so that only

three or four are sufficient to provide global coverage. Because the cost of satellite transmission is not related to distance, it is commercially competitive in rural or low-density areas (e.g., remote islands), where the high marginal costs dissuade other types of providers, particularly fiber optics providers.

The terrestrial counterpart of the satellite is the earth station. There are tens of millions of earth stations located worldwide, ranging in size from 0.5 to 30 m (meters). The vast majority, however, can only receive information, not transmit it (i.e., downlink only). When microwave signals are sent over great lengths and become broadly diffused, earth stations require large, powerful antennas to receive them. The distribution of the world's 483 publicly owned earth stations designed for international traffic in 2004 reveals that they are concentrated in the largest and wealthiest countries, particularly the United States, which, with 70, has vastly more than any other state.

A Brief History

The origins of the satellite industry lay in rocketry developed during World War II. Starting with the Soviet Union's launch of Sputnik in 1957, satellites played a key role in the militarization of space during the Cold War. The first U.S. satellite, Explorer I, was put into orbit 1 yr. later. Throughout the Cold War, satellites were instrumental in the discursive scripting of geographic

space, its ideological construction within hegemonic modes of understanding, shared by politicians, military planners, and the media, that were typically infused with the indiscriminate “othering” of the communist foe. The world’s first spy satellites, a series of 95 launched under the Pentagon’s Corona project, revolutionized Western understanding of the Soviet Union. Draped in secrecy, the Corona reconnaissance system offered accurate images of the vast Eurasian landmass, allowing the location of military facilities (especially long-range missile silos) to be pinpointed. The United Nations’ Outer Space Treaty of 1967 attempted to limit the militarization of space, an inconvenience to military planners that has largely been cast aside. In 1969, American military satellites were coordinated in the Defense Satellite Program to provide continuous, comprehensive, and seamless coverage of the Earth’s surface.

As the resolution and accuracy of military satellite imagery progressed over time, civilian uses followed accordingly. The visual power of satellites is usually expressed in terms of the length of the smallest feature that analysts can see when photographic processing is pushed to its limits. The exponential improvements in this capacity are evident in the changes from the early Landsat photos of the 1970s, with a resolution of 60 m, to the current generation of spy satellites, which can identify objects 5 centimeters in length. When satellites were the exclusive purview of the military worldwide, nations jealously hid the abilities of their surveillance systems so that foes would be less likely to evade and counter them; today, commercial providers boast openly about their systems’ powers of resolution.

Gradually, civilian applications assumed an increasingly important role in the satellite industry’s development. The first of these included the Landsat satellites launched by NASA (National Aeronautics and Space Administration) in the 1970s. The major difference between military and civilian purposes involved the shift in emphasis from surveillance to communications; although the technology remains important in both respects for military purposes, in the civilian domain, communications remains the dominant application. In 1962, the United States launched AT&T’s Telstar, the world’s first communications satellite. In the 1960s, NASA initiated the Syncom

series, which allowed television companies to initiate satellite transmission of programs, ultimately leading to an explosion of home broadcasting in the 1990s. The first privately owned satellite, Early Bird (Intelsat 1), was launched in 1965 and operated by Western Union. The first Soviet civilian satellite, Molniya, launched in 1965, was intended for purely domestic communications, in contrast to the American Early Bird, which was designed for international purposes.

Since the late 1950s, the world has launched more than 5,500 satellites; the vast majority were sent into orbit by the United States, which launched 1,854 before 2004, and the USSR (or Russia, since 1991), which launched 3,183. However, expanding commercial prospects gradually induced other countries to acquire the capacity to launch satellites. In 1973, Canada inaugurated the Anik satellite; France followed suit with the Spot and Telecom systems in the 1970s and 1980s, respectively; in 1977, Italy launched Sirio and Japan, its Sakura.

Regulating the Global Satellite Industry

International regulation has long been an important force shaping access to satellite technology, market structure, pricing, and its uses over time. The international regulation of telecommunications dates back to the International Telegraph Union in 1865, which later evolved into the United Nations’ International Telecommunications Union (ITU). The United Nations’ Outer Space Treaty, signed in 1967, constitutes the legal basis for extending international law into outer space, including the principles governing its exploration and use for purposes of communication.

A key issue in international regulation concerns orbital “parking spots,” particularly the coveted “geostationary gold,” which are allocated by the ITU. The ITU as an arena in which satellite geopolitics unfold confronts a dilemma between states already occupying slots and newer entrants demanding their own, who often feel that early users enjoy an unfair advantage. Newer claimants, typically developing countries, call for abolition of the currently existing “first come, first served” policy, which favors the economically advanced states. Such tensions reflect the fact that

satellites created a new resource—geostationary slots—but the world community lacks the means to allocate it with considerations other than profitability. Because the total number of orbital slots is limited by the physics of rotation and problems of bandwidth spillover, the steady growth in satellites has generated increasingly crowded conditions, with fewer degrees of orbital arc between them. Within countries, national communications boards (in the case of the United States, the Federal Communications Commission, or FCC) assign slots to private firms, generally via open auctions.

Two related issues closely associated with international regulation concern the allocation of electromagnetic frequency spectra and spillovers from satellite footprints. The former, the ITU's most successful area of jurisdictional competence, is accomplished through the World Administrative Radio Conference (WARC), which, through a series of international conferences and agreements, provides legal protection for the engineering lifetime of a satellite but does not allow states to enjoy unlimited control over a given frequency. The ITU must also address the conflict between the technological capacities of satellites and national sovereignty that occurs when signal footprints exceed the borders of a target country, which depends on the size of the footprint and the performance of the receiving earth stations. States that seek to restrict the imports of foreign media—including much of the Muslim world and the former Soviet bloc—have typically found it impossible to assert national control over global flows of information beamed from above. Such “externalities” point to the bleeding of the distinctions between foreign and domestic policy that communications technology has accelerated in this period of rapid globalization.

By far the largest and most comprehensive organization involved in the regulation of global satellite traffic is the International Satellite Organization (Intelsat), a private organization headquartered in Washington, D.C., with representatives from governments around the world. To expedite the entry of commercial providers in the satellite market, the U.S. government initiated a regulatory framework conducive to the growing interests of private firms. In 1962, Congress passed the Communications Satellite Act, which

established the privately owned Communications Satellite Corporation (Comsat), which enjoyed a monopoly over international satellite service to and from the United States for the next generation of satellites. Comsat became the nucleus of Intelsat in 1964, with Early Bird providing its early fleet, and originally owned one half of its shares; it remains the intermediary between Intelsat and the U.S. government and telecommunications industry. The organization started with 19 signatories from the economically developed world but excluded the Soviet bloc; today, 201 states are represented.

Intelsat is not regulated by any public body and is accountable only to its owner members, the stock holders. Political power is concentrated in the Board of Governors, in which voting power is proportionate to the share of ownership, with a dues structure similar to that of the United Nations. Not surprisingly, the United States is the largest contributor, responsible for almost one quarter of Intelsat's total revenues. Most international telephone calls (which generate two thirds of its revenues) are routed through Intelsat's satellites, each of which carries tens of thousands of voice circuits, although international television is its most rapidly growing source of revenue. Other services include radio, integrated digital services, business-to-business services (e.g., orders, inventory control), financial data transmission, rural community services, news gathering, and weather reports. Although it was initially erected to serve only international traffic, Intelsat began to offer domestic services as well in 1976. Today, it remains by far the world's largest provider of domestic (as well as international) satellite services through leased transponders and provides a means to regulate orbits and frequencies as well as for international pooling of financial resources and sharing of risk.

Intelsat's infrastructure dwarfs that of any single state or organization. It owns and operates a fleet of 25 high-powered spacecraft in geosynchronous orbit over the Atlantic, Pacific, and Indian oceans—far more than any other network; indeed, Intelsat's size allows it to boast of being virtually the only truly global satellite system. Intelsat's 433 earth stations, which constitute 79% of the world's earth stations capable of international traffic, give it a near-monopoly

status. While Intelsat's clients are primarily corporate, it maintains a nonprofit side as well, a policy designed in part to ameliorate concerns among less developed nations that the organization serves only the interests of the West. The Intelsat signatory agreement calls for global averaging of prices between high-traffic routes to subsidize the less profitable ones, a measure intended to ease the costs on poorer nations; thus, all nations pay the same price, regardless of the actual service costs—an attempt to provide ubiquitous coverage. Similarly, Peacesat (the Pan Pacific Education and Communication Experiments by Satellite Project) provides health, education, and research services over the Pacific Ocean using NASA satellites.

Because Intelsat's member states were allied with the United States during the Cold War, it was long viewed by the Soviet Union as an instrument of U.S. domination over the world telecommunications network. To counteract Intelsat's hegemony, the USSR developed its own system, Intersputnik, headquartered in Moscow. Although Intersputnik was proposed in 1968, it did not begin operation until 1974, and today it consists of eight geostationary satellites (and several nongeostationary ones) and 32 earth stations capable of international traffic. Traffic on the Intersputnik system, however, is only a fraction of Intelsat's. During the 1980s, Intersputnik's members were limited to the USSR and client states in Eastern Europe, as well as Iraq and Syria. With the collapse of the USSR in 1991, other nations sought access to its network, leading the United States, Canada, Japan, and China to join, while the Central Asian republics dropped out.

In contrast to Intersputnik, which was intended to rival Intelsat, three other, smaller satellite systems were erected to complement the organization. Concerned that the prevailing networks provided insufficient coverage of maritime regions, the International Maritime Organization, the UN agency concerned with safety at sea, initiated Inmarsat in 1973 to provide maritime satellite services. Because maritime communications are a low-volume and hence low-revenue market, they had been ignored by Intelsat, which catered to corporate interests. Headquartered in London, Inmarsat is a nonprofit cooperative of

28 countries, including the United States, Russia, China, India, Japan, Australia, Brazil, and most of Europe. Today, its network consists of four geostationary satellites and 23 earth stations that assist aviation and shipping firms, governing, among other things, distress calls, ship-to-shore communications, ship-to-ship telephony, electronic data interchange, and weather updates and providing safety information about high-traffic regions and potential hazards.

The European Telecommunications Satellite Organization formed Eutelsat in 1977 to complement Intelsat services over the European continent, including television, telephony, and data communications for computer networking. Coordinated by the European Space Agency and headquartered in Paris, Eutelsat wholesales its capacity (24 satellites and 23 earth stations) to national carriers, which in turn sell it to retailers. The end of the Cold War allowed Eutelsat to expand into Eastern Europe, so that today 23 nations are its members, including Germany, Turkey, Armenia, and Belarus.

Developing countries also complemented Intelsat with their own regional systems. In 1976, the Arab League formed Arabsat, a regional satellite system. With only 17 members, three satellites, and 18 earth stations, however, Arabsat is small, and its capacity is largely underused. One half of its shares are owned by Saudi Arabia. Political differences among Arab nations have hindered its growth: For example, Egypt was barred from membership between 1979 and 1989 because it signed the Camp David Accords. Given the authoritarian control exerted by many Arab governments over flows of information, frequent prohibitions exist against the import of satellite programs deemed immoral or decadent. Other, similar systems include the Regional African Satellite Communications System (Rascom) and, in South America, the Condor Alliance of Andean Nations. This brief overview demonstrates the key role of the nation-state in the changing regulatory organization of the industry, the contradictions between state and market imperatives, their changing boundaries and relative significance, and the intractably geographical nature of the industry. Despite the fact that satellites were designed to annihilate space via instantaneous communications, uneven social and spatial access

Figure 1 Location of the world's international satellite earth stations. In 2004, 483 earth stations were sufficiently large to upload or download information from satellites in geosynchronous orbit.

Source: Author.

to satellite technology has been a key feature of the industry since its inception (Figure 1).

The Contemporary Satellite Industry

In the post-Cold War era, Intelsat has been faced with two major sources of competition. The first stems from national satellite systems erected by individual nations. Indonesia, the first developing nation to use satellites for domestic connectivity, launched several generations of its Palapa ("Unity") satellites in the 1980s to provide services to all 27 provinces and recently began to sell them to neighboring ASEAN (Association of Southeast Asian Nations) countries as well. India initiated the Indian National Satellite System (Insat), primarily to provide low-cost educational services to remote villages and, in 1981, launched its first indigenous telecommunications satellite, the Ariane Passenger Payload Experiment. In the 1990s, India put into orbit three Insat satellites, thus joining the small group of nations that not only build but also launch these devices. Brazil's BrazilSat system leased its first satellite in 1974 and launched two more in the 1980s, expanding its domestic network with 21 earth stations. In the

same vein, Mexico, China, France, Turkey, and Thailand all initiated national satellite systems, some with their own launch capabilities. Unlike complementary networks such as Inmarsat or Eutelsat, national satellite systems are designed explicitly to bypass Intelsat.

The rapidly growing market for satellite services has been driven by the explosive growth of cellular telephones, which now outnumber landlines worldwide. Wireless technology (cell phones and satellite television) was made feasible through the deployment of a series of Direct Broadcast Satellites (DBS) that can transmit directly to small rooftop antennae or cellular towers. Unlike the large, expensive geostationary satellites, DBS can orbit in a variety of orbits designed to maximize the flexibility and utilization rate of the network. The growth of the wireless market in some respects has given the satellite industry a new lease on life, and it has become an increasingly important source of revenue.

Finally, the satellite industry as a whole has been besieged by mounting competition from fiber optics carriers, the mode of choice for many large service firms due to the security they offer. The competitiveness of satellites versus fiber lines depends on the transmission distance; generally,

satellites are more cost-effective over very long distances. However, fiber optics allows for greater security and is heavily favored by large corporations for data and voice transmissions and by financial institutions for electronic funds transfer systems. Capacity growth in the fiber optics industry has been particularly explosive, and transmission costs have dropped accordingly, which extended the break-even distance with satellite competitors, sharply eroding the latter's market share. Today, fiber optics carriers represent 86% of worldwide transmission capacity, including 87% across the Pacific Ocean and 80% across the Atlantic Ocean. The results of this conjunction of circumstances—deregulation, heightened competition within the industry, and devastating inroads made by fiber optics carriers—have led to the recent slump in the satellite industry, with decreased demand, bankruptcies, and declining orders for new satellites.

Conclusion

Satellites as both mechanisms of observation and a means of communication reflect, and in turn feed back into, terrestrial politics in many ways. Born of Cold War rivalry, satellites played a key role in the militarization of space: The footprints of those in geostationary orbit create a spatial field of power subject to the gaze and manipulation of military planners. Although the military's role in the satellite industry has declined, military uses continue to remain an important segment distinct from civilian applications. The geography of large international earth stations, the foundational technology on which participation in this sector relies, reflects the persistent schism between the developed and underdeveloped worlds, and, to a lesser extent, the legacy of the Cold War. Hence, while satellites float thousands of kilometers overhead, the determinants of access and use are firmly grounded in terrestrial politics.

SAUER, CARL (1889–1975)

Carl Sauer was a towering figure in geography and in the intellectual life of America during the middle of the 20th century. The term *polymath* has often been applied to him because of his wide knowledge in the humanities and natural sciences, especially where these impinged on his research interests in Ibero-America, plant domestication, early humans during the Pleistocene, and the destructive exploitation of Earth. He displayed an ability to link diverse evidence together and then take bold, intuitive leaps and speculative sweeps. The historical past, ecological thinking, and methodological diversity were all central to his understanding of the contemporary cultural landscape. Cultural geography became associated with his name, and his many students spread the word about the Berkeley School of cultural geography. He held strong views about the importance of scholarship. His work was characterized by independence of thought, opposition to academic bureaucracy, sympathy and identification with rural folk, a concern for cultural diversity and environmental quality, and a distaste for the technological and scientific “fix,” particularly the solutions offered by the emerging social sciences after 1940.

Background and Reputation

Sauer was born in Warrenton, Missouri, on December 24, 1889. He took his first degree at the Central Wesleyan College, Warrenton (now defunct), moved to Northwestern University in 1908, and then completed his PhD in the first full-fledged department of geography at Chicago University in 1915, under the varied and different influences of Ellen Churchill Semple, Harlan Barrows, and the geologist and charismatic head of department, Rollin Salisbury—all of whom had a lasting influence on him. During those years, he was commissioned by the state geological department to write a geography of the Upper Illinois Valley, and he also completed the fieldwork for his PhD on the Ozarks. He then taught at the University of Michigan until 1923, when he moved to Berkeley, where he taught for 34 yrs. (years), 32 yrs. as chair of the geography department) and established one of the most distinctive graduate schools of American geography, one that would always be associated with cultural geography. He was also one of the chief advisors to the Guggenheim Foundation from 1935 to 1955 and to the social sciences division of the Rockefeller Foundation for nearly as long. After he retired in 1955, he enjoyed 20 remarkably productive years that saw the publication of four books and a score of influential papers.

The Cultural Landscape

Sauer rejected the prevailing ethos of human geography as environmental determinism, and in his work on the Ozarks, Illinois, and the Economic Land Survey of the Michigan Cutovers, he promoted a more humane and culturally nuanced human geography that took full account of the natural sciences, ecology, and the historical record and exhibited an empathetic understanding for both the people and the landscape. Much evidence was gathered through fieldwork, on which he put special emphasis.

On arriving in Berkeley, he found the social anthropologists Alfred Kroeber and Robert Lowie agreeable intellectual companions, which reinforced the cultural bias. In a famous essay, “The Morphology of Landscape” (1925), he established the primacy of human agency in the

formation of cultural landscapes fashioned from a natural landscape by a culture group and the importance of a time-based approach. “Morphology” became one of the most influential and debated papers in American geography during the ensuing decades. During the 1930s, he started substantive fieldwork on early settlement and society in Southern California, Arizona, and Mexico. These investigations drew him into the controversy about New World plant domestication and origins and into collaboration with botanists, archaeologists, and ethnologists, whom he considered as more congenial intellectual company than most geographers, whom he found to be shallow, intellectually ignorant, and consequently ignored.

Destructive Exploitation

Even in his student days, Sauer was struck by the ability of humans to deform and destroy the Earth. From the Ice Age onward, humans had changed vegetation types and distributions. His work on the Michigan Land Economic Survey, and his later role as advisor to the U.S. Soil Conservation Service, working in the eroded lands of the Southern Piedmont, reinforced this conviction. His fieldwork and knowledge of Latin and Central America and their history suggested that the Spanish conquest had led to a similar devastating and permanent impoverishment of the land and of its cultures and societies, causing catastrophic population decline. The diffusion of technologically superior societies could affect cultures and human life just as much as it could physical resources. Papers written by him between 1936 and 1938 on the human impacts were truly revolutionary in their condemnation of the destructive social and environmental impact of European imperialism and colonialism.

Agency of Humans on Earth

Sauer’s scholarly reputation led to his being asked to organize a major symposium of international scholars on “Man’s Role in Changing the Face of the Earth” in 1956. But because of his pessimism about the future world, he handed over part of the organization to Marston Bates and Louis Mumford and “retreated” into a consideration of “how we got to where we are.”

Somehow, humans had to rise above their mindless, short-term exploitative mode and try to conserve “a good Earth.”

Diversity and Scholarship

In later life, Sauer became increasingly critical of Western technology, ways of life, and intellectual trends. Americans seemed to think it a civic duty to “live beyond one’s means,” while communities were disintegrating under the pressures of mass production (“commodity fetishism”). Globally, the “imperialism of production” was as bad as the old, colonial imperialism, and mass culture was destroying older and less robust societies. Social theory, according to Sauer, was insidious as it led to cultural hegemony and homogeneity and the end of diversity and individual action and scholarship. It was the inherent pluralism and diversity of nature and culture that stimulated curiosity about the world, which was the essence of geography.

Sauer’s simply articulated ideas and pithy language had a resonance with many intellectuals and activists, who extolled his work as an example of cultural and ecological sensitivity and respect, tinged with deep historical insight and scholarship. Sauer, however, was a paradox, because although he was deeply conservative, his nonconformity and questioning were deeply inbred. He was aware that he was “out of step” with his colleagues and other intellectuals, yet his profound concern with conservation was never formally “environmentalist,” and indeed, he thought that the early movement was little more than an “ecological binge.” The legacy of his work in geography and Earth history is wide-reaching because he anticipated brilliantly society’s disenchantment with progress, science, the elimination of diversity, and the degradation of the environment and the need to bridge the gap between the social sciences, the humanities, and the life sciences.

SCALE, SOCIAL PRODUCTION OF

One of geography’s core ideas, scale has become a hotly contested, even chaotic, concept. Until the 1980s, scales (such as the national or regional scales) were frequently employed, but little time was devoted to theorizing scale itself. Scale was a taken-for-granted concept used to impose organization and order on the world. A much vaunted “scale debate” emerged during the 1980s, developed through the 1990s, and erupted in the early 2000s. The debate centers on whether scale is a mental device for categorizing and ordering the world or whether scales exist as material social products.

A Marxist “Theory of Scale”

Linked to processes of globalization, localization, and regionalization, scale became a fundamental concept for political geographers in the 1980s. The works of Peter Taylor and Neil Smith were pivotal in identifying the different levels at which processes of the world economy are manifest. Both identify a nested hierarchy of scales running from the global to the local. Taylor’s three-level model of the modern world system identified the

world economy, nation-state, and locality, while Smith highlighted urban, regional, national, and global as critical scale categories. Introducing for the first time a “theory of scale,” this approach was not without its critics. Scales were rather more fixed than is commonly accepted today. The result saw scale categories reified as distinct levels of analysis, each with its own disciplinary following. Integration of analysis across scales and/or at multiple scales therefore proved difficult, with many arguing that scale lacked practical as well as rhetorical value. Finally, this first cut at a theory of how scales are produced was heavily inscribed with Marxist ideas of materialism. This is to say that scales are real social products (not simply handy conceptual mechanisms for ordering the world) and they emerged out of the dynamics of capitalist accumulation.

Scale as a Dynamic Construct

Rather than see scale as a nested hierarchy, debate in the 1990s focused on discursive and relational notions of scale that moved away from scale as a taken-for-granted to scale as a dynamic concept. This debate took place largely in the journal *Political Geography*, with social constructivist approaches demonstrating how scales are the negotiated outcome of social and political struggle. More than this, they showed how scales are always in the process of being produced and reproduced, and it was in this context that the concept of a politics of scale was introduced and developed. To compensate for the overreliance on the rhetorical value of scale in the 1980s, accounts from the 1990s also argued that scale politics are not found in theoretical discourse but in real-world practices of social conflict and struggle. Notable empirical studies from this time focused on telecommunications, labor restructuring, and political parties to highlight how scales are socially constructed, not ontologically pre-given. Scales such as the national and regional were no longer seen to be part of some logical hierarchy between global and local but as *actively* created by political and economic processes. In other words, scales are not “out there” waiting to be used but must be brought into being and given meaning.

In such an approach, the scales at which social actors and processes operate cannot be conceived

of as disconnected from the actors and processes that create them. Often quoted here is the example of the transnational corporation, for these firms do not simply adapt their activities to a pre-defined global scale but must themselves become global by actively constructing their own global scale of operation. Emphasizing this constructivist approach to scale is the notion that firms go global by globalizing their operations to keep up with the increased hypermobility of globalized capital.

One criticism to emerge from this body of work was against the assumption made by some materialists that the local is a “natural” or “default” scale. In making this argument, all social actors begin as “local” actors before moving on to become regional, national, and, finally, global actors. The global scale was thus something for actors to aspire to. Being global was a measure of success and reinforced this hierarchy of scales from local to global. In response, it was argued that the local is no more natural than the other scales and is produced in the same way. In a world where many predicted the “death of distance” and the “end of geography,” authors quickly highlighted the importance of nurturing place-based and site-specific nodes of dense economic, social, and political activity in a globalizing world. Understanding the processes by which social actors embed themselves locally was thus seen to be as important as understanding how they extend themselves globally. In sum, scales were not conceived of as fixed entities static in space but in terms of a process where social life is constantly being made and remade by social actions.

Scale or No Scale: That Is the Question

The most recent debates over scale have been found in journals such as *Progress in Human Geography* and, later, the *Transactions of the Institute of British Geographers*. Work at the beginning of the 21st century has focused on moving the debate outside the narrow economic confines of theorizing how scales are forged out of struggles around capitalist production and its uneven development. These productionist views were criticized for overlooking how issues of social reproduction and consumption have shaped, and continue to shape, the construction of scales. In expanding the concepts of scale to

encompass issues of reproduction and consumption, noncapitalist social relations (such as patriarchy) have been shown to underpin the production of certain key spaces (e.g., the home) and scales (e.g., the household/domestic scale). However, this expansion has not been without its critics. Calls for *household*, *domestic*, and *neighborhood* to be more centrally located alongside *local*, *regional*, *national*, and *global* in a broader scalar lexicon raised concerns over the degree to which geographers use scale when referring to things that could just as easily be deemed place, locality, territory, or space. Most recent work has thus centered on the degree to which the analytical powers of the concept of scale have been diluted by its perceived overuse and misuse and, most important of all, what this means for the future of the concept in human geography.

Arguing that the concept of scale has been misused and, therefore, diluted by those seeking to understand the political struggles taking place *within* relatively self-enclosed spatial units (such as the household or territory), those seeking to “protect” the concept of the politics of scale suggest that its analytical power should be maintained and can be retained if applied only to exploring processes of spatial scaling *among* geographical scales. In other words, the geographical concepts of place, locality, territory, and space should be invoked to refer to political struggles taking place within relatively self-enclosed spatial units, and the concept of the politics of scale should be used to refer specifically to the process of scaling, where multiple spatial units are established, differentiated, and hierarchized in relation to one another. Drawing a distinction between the “production of space” and the “production of scale”—to affirm the analytical power of the concept of the politics of scale—has, however, been challenged by those who continue to see notions of scale as privileging a view of the world as hierarchically constituted. Notions of scale are hereby seen to convey the sense that activism and politics operate through vertical hierarchies and a related tendency to see one scale (especially “the global”) as privileged over others. From this perspective, the problem with scale is not the misuse of the concept but the concept itself. In 2005, Sallie Marston, John Paul Jones III, and Keith Woodward took the previously unheralded

step of calling for scale to be expurgated from the geographic vocabulary and notions of scale to be abandoned. For them, scalar analysis operates within a conceptual straitjacket, limited to viewing change as either downward (from global to local) or upward (from local to global), while attempts to integrate vertical imaginaries with network formulations are deemed inadequate for overcoming this “foundational weakness” of hierarchical scale. Rejecting not only the “up-down vertical imaginary” but also the “radiating (out from here) spatiality” of horizontal thought, Marston et al. argue for an alternative, “site-based” ontology that does not rely on *any* transcendent predetermination—be it the “local-to-global continuum” in vertical thought or the “origin-to-edge imaginary” in horizontal thought. Put forward as an alternative to scale, this site-based ontology is deemed to flatten space into multiple interconnected sites and thus render scale a redundant concept in human geography.

The most provocative of interventions into the scale debate has witnessed an explosion of interest in scale and scalar geographies. Most reactions argue for a retention of scale, despite its weaknesses and the varying degrees of sympathy with authors’ frustration with these. One point most critics agree on is the false dualism created by debunking scale and privileging site (i.e., scale vs. site), a symptom of what many are coming to see as the theoretical, methodological, and empirical trap of one-dimensionalism—the privileging of a single dimension of sociospatial relations (in this case “networks”) over another (“scale”). This, it is argued, sees the bending of a concept to expand its analytical and empirical scope in order to include an ever-increasing portfolio of phenomena, a process that over time renders the concept increasingly imprecise, diluted, and blunt. With this in mind, perhaps the question for the next decade is not whether scale should be retained but how a carefully defined abstraction of scale interconnects with the other dimensions of sociospatial relations (e.g., territory, place, networks).

SCALE IN GIS

Scale has many connotations in geographic information systems (GIS) research and education. Among its most frequent uses, scale captures the relationship between distances in the real world and the distances among objects on GIS maps and in spatial databases. In this sense, scale is the level of reduction associated with representing Earth's features in GIS and cartographic databases. There is also the related concept of spatial scale, which deals with the level of resolution or granularity of spatial objects in terms of what are the finest discernable details. Along similar lines, the temporal scale associated with spatial data

indicates how frequently data are collected for the same area. Last, the notion of a scale is often used in GIS project management and modeling to gauge the effort required to complete a given set of tasks and/or to describe the extent of the area covered by the study.

Map Scale

In map design and production with GIS, it is very useful to think of scale as the ratio of distance on the map to distance on the ground. This is the representative fraction, and with a map of 1:2,500, 1 inch on the map equals 2,500 feet on the ground (metric units may be used as well). A map at 1:2,500 is known as a large-scale map because the fraction (1/2,500) is large compared with other possible map scales. Large-scale maps are particularly good at showing local-level details over a relatively small area.

As seen in Figure 1, land parcel boundaries for a neighborhood are mapped at a scale of 1:2,500. It is easy to pick out the detail and characteristics of the parcel objects at this scale. If we change the scale to 1:35,000, which is generally considered to be a medium scale, many more of the parcel boundaries come into view for this particular area. But it becomes very difficult to visualize subtle differences in the parcel objects' shapes. Some parcel boundaries are visible at this scale, although there is a great deal of obfuscation in denser areas. Changing the scale to 1:1,000,000, we can no longer see any detail within the study area, and the general shape of its exterior boundary is no longer crisp. As such, maps with scales in the neighborhood of 1:1,000,000 are known as small-scale maps and are good at showing less detailed features over large areas. To put this scale into better context, the U.S. counties surrounding this neighborhood are also shown in the figure. The many large counties are well represented at this scale, but the neighborhood-level detail is lost. Therefore, a key issue in dealing with scales is to select one that is appropriate, given the mapping task at hand.

Spatial Scale

The spatial scale of a given data set is the smallest discernable unit of geography contained therein.

Figure 1 Sample neighborhood mapped at three scales: (A) 1:2,500, (B) 1:35,000, (C) 1:1,000,000

Sources: Parcel data from Franklin County Auditor, Ohio; county data from the U.S. Census Bureau.

It is also known as spatial resolution. Imagery data, for example, are widely evaluated based on how small a unit area one of its individual pixels or cells represents. Imagery captured from aerial photography routinely has a high resolution such that pixels represent areas of less than 1 m² (square meter). Imagery captured from a satellite station may also approach the resolution of imagery taken via aerial photography, but many satellite platforms offer much coarser resolutions, some greater than 1,000 m. The temporal scale of a data set, or the frequency of data collection for a given area, is also of relevance. Depending on the area, aerial photography, for example, can be quite variable in terms of how often new data are collected. On the other hand, many satellite-based forms of spatial data collection follow a regular temporal cycle. Spatial data collected at such regular cycles are useful in many applications, particularly those where careful monitoring of the changes in the landscape is required. In this way, users must not only consider the level of detail

associated with a data set, they must also consider its frequency of collection if there is a temporal dimension to their study.

There are many analytical situations where the spatial scale of the input data is an important concern. Many socioeconomic variables, particularly those associated with irregularly shaped census and enumeration units, are often available at a variety of spatial scales or aggregations. For example, median household income is available not only for counties in the United States but also for each census tract composing the counties and each block group composing the tracts. Generally, it is best to use the most disaggregated or resolute spatial data one can find given the aims of the study. This is because finer spatial data do a better job of representing the true spatial distributions of phenomena as they involve less generalization. However, there are cases where having extremely detailed data may not be necessary and may even limit some analytic capabilities. Some operations (e.g., facility location models) are sensitive to the number of

input units and may require a prohibitive amount of computer processing time if used with too detailed a data set. Thus, balancing the representativeness of the data with the limitations and constraints imposed by the specific GIS tools or modeling techniques is often a concern.

Project Scale

Certain aspects of designing and completing GIS projects may be qualified in terms of scale. For example, if a government agency or private business were building itself a GIS department from the ground up, the size of that department as perhaps measured by the level of staffing required and/or its hardware needs might be qualified as a small- or large-scale GIS implementation project. In a slightly different context, the work involved in completing a particular GIS-based project may be a matter of scale. For instance, if substantial primary data collection were involved or a large amount of time is spent on data manipulation, processing, and/or analysis, such efforts could be described in terms of their scale. Last, scale may be used to indicate the extent of the area analyzed in a given GIS project, with larger-scale projects referring to studies involving greater coverage. Clearly, each of these examples shows that the use of scale to describe aspects of GIS projects is subjective—for example, one person's large-scale project may be another's small-scale project.

SCHAEFER, FRED (1904–1953)

Fred Schaefer was a founding member of the department of geography at the University of Iowa, remaining there until his death in 1953. Schaefer is revered as a pioneer of the “quantitative revolution” in geography, for providing the greatest philosophical impetus for a scientific geography, although he died before many of its subsequent adherents met him.

Schaefer was born in Berlin and was an undergraduate at the University of Berlin (1928–1931) and a statistician for the city. But as a member of the Social Democratic Party, he fled from Nazi Germany in 1931 to Britain and then to the United States in 1938. He worked at an American Friends Service Committee refugee camp in Iowa before he joined the University of Iowa. His radical politics led to a degree of harassment in the period from 1946 to 1952.

His fame rests on the 1953 publication, which appeared just after his death, of an article in the leading American geography journal, the *Annals of the Association of American Geographers*, titled “Exceptionalism in Geography: A Methodological Examination.” The paper had an electrifying effect on the discipline. Schaeffer had written about the possibility of a theoretical scientific geography as early as 1943 and taught the works of the leading location theorists (e.g., Christaller, Loesch, Thünen, Hoover) as early as 1950.

That the manuscript was published is remarkable; he was helped by Harold McCarty, chair at Iowa and an early advocate of the quantitative revolution. This revolutionary document was at the same time a methodological and philosophical attack on the dominant paradigm of geography as “idiographic,” or as a synthetic, descriptive field, as laid out in Richard Hartshorne's *Nature of Geography*, and a call for a normal scientific approach to geography based on a search for geographic laws concerning spatial relations—a “nomothetic” approach. The article was denounced by Hartshorne and other defenders of traditional geography but became an article of faith for the younger generation of economic geographers (after 1955), who were determined to develop geography as a spatial science.

SCIENCE, TECHNOLOGY, AND ENVIRONMENT

The relation between science, technology, and environment is one of the key issues of late modernity. At the beginning of the 21st century, the impacts of science and technology on human life and the natural environment are greater than ever. Whereas an affirmative view on this development for a long time presumed that science and technology help solve the problems of humanity, critical perspectives on the human-nature relationship increasingly found voice during the second half of the 20th century (among others, the social scientists Max Horkheimer and Theodor Adorno, the philosopher Hans Jonas, and more recently the sociologist Ulrich Beck). Of course, this is not a new phenomenon, since skepticism regarding science and technology is as old as science and technology themselves. But because the negative effects of modern domination of science and technology over both human and nonhuman life as well as on abiotic realities have reached a global scale, the demand for a reconfiguration of the use of science and technology to transform nature emerges. Thus, issues pertaining to the consequences of science and technology are currently being discussed by politicians as well as by social and natural scientists. Geography, which as a discipline, throughout its historical development, was concerned with nature and the environment (from the first descriptions of the Greek

explorer Herodotus in the 5th century BC until the modern-day analysis of geo-ecosystems, or the study of the social construction of nature), is a key science in environmental discourse.

Irrespective of their arguments, most critics refer to the rationalization and instrumentalization of the natural environment that has attended modernity. Rationalization means an abstract, mathematical representation of nature, based on reason rather than faith or myth. Instrumentalization, on the other hand, focuses on the benefit to humans in human-nature relationships. Both processes, critics say, lead to an alienation of humans from nature followed by the form of maladjustment of people to the environment that is currently called the ecological crisis. Despite a consensus about the critical role of science and technology in the process of modernization, there is confusion about the differences between them. Therefore, a review of these two social activities will be given in this entry. Also, the role of science and technology in the development of the ecological crisis will be examined.

Science and Technology

It is often presumed that science and technology differ in the following way. Science produces knowledge about the world, regardless of practical ends. Technology, in contrast, is the application of scientific knowledge to meet human needs. From this perspective, science precedes technology, which is a mere application of the scientifically discovered rules and laws of nature. This idea of the relationship between science and technology is flawed in at least one way. It misses the fact that science and technology are two interrelated but different domains of human activity, distinct in their aims, procedures, and historical development.

Science

The term *science* has its origins in the Latin word *scientia*, or knowledge. Thus, *science* describes the attempt of human beings to produce objective, reliable knowledge about the world. Sometimes the term *science* is also used to designate the outcome of this search—that is, the body of (scientific) knowledge. But this notion does not

capture the most important feature of science—that it is a social activity.

It is by the application of certain methods that the outcome of the search for knowledge is regarded to be *scientific*. Consider other areas where particular capabilities are necessary. Craftsmen, for instance, also possess knowledge about the functioning of the world, but we would not necessarily agree that their knowledge is scientific. When scientists do their work, however, in the majority of cases they follow rules that their fellow scientists agree to and produce knowledge that is testable (verifiable or falsifiable). A clear illustration of this is provided by the role of experimentation in physics. A laboratory experiment has to be reproducible in order to obtain status as scientific knowledge.

Historically, the first objective of science was to describe and explain natural phenomena. Thus, science was first of all natural science, which was concerned with finding or formulating general laws of nature. Newtonian physics is a classic example of the functioning of modern science. Even though there was “scientific” research during Greek and Roman antiquity, as well as in the Middle Ages, the foundations of modern science were laid in the 16th century. In the course of the “Scientific Revolution,” works of astronomers such as Galileo Galilei, Johannes Kepler, and Sir Isaac Newton were a major step forward in understanding the physical world. Equally, the later works of the founder of modern chemistry, Robert Boyle, and the zoologist Carl Linnaeus established the notion of nature and the environment as scientifically comprehensible and technically manageable.

In contemporary understanding, however, the explanation of natural phenomena is only one domain of science. Science can now be divided into two branches: the natural sciences and the social sciences. The social sciences try to understand human action. As a distinct field of research, the social sciences are relatively young, beginning only by the end of the 19th century. First shaped according to the model of the natural sciences, the social sciences soon developed their own concepts and theories. Two of the key figures of the emancipation of the social sciences from the natural sciences were the French sociologist Emile Durkheim and the German sociologist Max Weber. They successfully pointed out that

the methods of natural science were not appropriate for analyzing social phenomena. Since the sphere of the social consists of meaning, or meaningful action, a type of science that does not capture meaning cannot make reasonable claims about this sphere.

Both the social and the natural sciences are, or can be, concerned with nature. Whereas the nexus of the natural sciences to nature is obvious, the social sciences, among other things, investigate human-nature interactions. Social scientists, for instance, pointed out that there is an important connection between cultural or religious systems and the way in which nature is perceived and used by humankind. They also advanced the notion that nature and the environment are socially constructed and the natural sciences have no exclusive access to the “real” nature but are one mode of construction among others.

As regards the role of science in modern society, scientific knowledge has ample influence on what people think about nature and the environment. Even though there might be other ways of knowing the environment (to which the specific standards of scientific knowledge do not apply), science seems to dictate the concepts of nature’s “real” nature.

Technology

The second dominant way in which humans relate nature to themselves is by technology. The term *technology* stems from the Greek words *technē*, meaning “craft,” and *logos*, which means “reasoning.” Thus, etymologically *technology* means knowledge about techniques. Techniques are human acts of transforming nature (or the physical world) and the results of these acts. A very simple technique is thus the transformation of a stone and a piece of wood into a hammer (which as a tool is then used for further transformative acts). Another technique is the domestication of the biotic environment, in the form of growing cultural plants. A third and very sophisticated technique is genetic engineering.

What these techniques share is that they involve the production of an artifact—an object (or biological structure) that would not have existed naturally and that serves a certain purpose. Hammers are used to extend a human’s muscle strength.

Using global position system equipment on a farm for precision application of fertilizers, pesticides, and herbicides, Northern Louisiana

Source: Bob Nichols, U.S. Department of Agriculture Natural Resources Conservation Service.

Plants are used for food supply. Genetic engineering is used to make organisms resistant to certain environmental influences. In this regard, the production of a hammer and the manipulation of DNA are nearly the same. What these techniques, on the other hand, do not share is the degree to which they influence the environment. While a hammer commonly has only a local, small-scale impact on its environment, the interference in biological structures such as DNA can change whole ecosystems up to the global scale.

The question of the implications of techniques points to the concept of technology, as opposed to technique. Technology in the strict sense is best conceived as the systematic analysis of the human use of techniques. As such, it not only involves knowledge about specific techniques in certain fields (e.g., expert knowledge about crop behavior

under different environmental circumstances) but also knowledge about the framing or use of the techniques—that is, the social context in which the transformation of nature takes place.

The everyday use of the term *technology* in both scientific and nonscientific areas points to a merging of the notions of technology and technique. Simply put, in the Anglophone tradition, the terms *technology* and *technique* are often used interchangeably. For instance, the concept of “information technology” involves both concrete technical solutions to problems of information, transport, and processing and knowledge about interrelations in this field.

By identifying goal orientation as the distinctive feature of technology, the differences between technology and science become obvious. Whereas scientific conduct invariably involves compliance

with rules and standards to secure objectivity to its findings, the only criterion that technology is judged by is its pragmatic success. Of course, modern science cannot be separated from the use of technologies, since science and technology closely relate to one another. Science uses technologies to make its findings, while scientific knowledge is applied to develop new technologies. Both science and technology contributed to or enabled the aforementioned rationalization and instrumentalization of nature in modernity. Science incorporated the abstract, mathematical conception of nature, and technology or technique is by definition goal orientation.

Finally, both science and technology are social activities. In other words, they are performed by agents, embedded in a system of beliefs, and equipped with certain stocks of knowledge and a set of needs and desires. What results from this understanding of science and technology is that the environmental change that is driven by (natural) science and technology can only be comprehended by drawing attention to the social dimensions of the two phenomena. One approach to highlight the role of science and technology in the process of modernization is Ulrich Beck's diagnosis of the ecological crisis and the risk society.

Ecological Crisis and Risk Society

The indication of the unintended consequences of the nexus of science, technology, and environment is not exclusively a phenomenon of late modernity. As early as 1864, the U.S. environmentalist and geographer George Perkins Marsh warned of environmental hazards caused by human action. The problems that emerged in the shift from preindustrial to industrial and then from industrial to postindustrial societies, however, reached a hitherto unknown dimension. The clearest manifestation of this process is the development of technologies, namely, nuclear fission, that potentially can exterminate all life on Earth. Furthermore, the widespread use of technologies such as synthetic pesticides has led to irreversible damages to both humans and the environment.

According to Ulrich Beck, the latter developments are signs of a new, reflexive type of modernization. Reflexivity in this context means that the "nontechnical" question of improving

human efforts to dominate nature is the prime concern of society today, but the technological development itself becomes the focus of critical questioning. Nuclear power is the best example of this process. Nuclear power, conceived as a form of taming nature to meet human needs, becomes reflexive in the sense that the risks and side effects of this technology are much more dangerous than nature itself. Late modern societies thus must face nature-related problems that they themselves have produced.

The role of (natural) science in this context is ambiguous. On the one hand, the complexity of the highly technologized world permanently demands expert knowledge. On the other hand, in late modernity, science no longer has the prerogative of providing an interpretation and definition of nature. To an increasing degree, politics and moral instances are part of environmental discourse. Hence, geography, as a discipline in both the natural sciences as well as the social sciences tradition, has a crucial role in the age of ecological crisis.

SCIENCE AND TECHNOLOGY STUDIES

Science and technology studies (STS) is defined as the interdisciplinary study of the social, cultural, and political dynamics that inform and shape science and technology and how these in turn inform and shape future society, politics, and culture. The premise adopted in STS is that science and technology are not value-free, apolitical activities as has tended to be assumed in “realist” accounts. Rather, science and technology are assumed to be informed by values, to be “framed” in ways that privilege particular (often expert) groups, to reflect particular “ways of seeing” the world, and to “perform” social relationships. For this reason, much of STS has sought to develop “socially constructivist” approaches aimed at understanding the role of science in apprehending, measuring, defining, and legitimating social reality.

This entry reviews the history of STS and how it has come to constitute a distinctive body of thought. STS is a subdiscipline with its own professional societies (notably the *Society for the Social Studies of Science* [or 4S] and the *European Association for the Study of Science and Technology* [EASST]), several high-profile interdisciplinary journals (*Social Studies of Science*; *Science, Technology, & Human Values*; *Science as Culture*; *Minerva*; *Public Understanding of Science*; *Science and Public Policy*), a series of *Handbooks of Science and Technology Studies*, and numerous university departments, courses, and degree schemes.

Phase 1: The Sociology of Scientific Knowledge

Throughout the 1970s, a program of research was developed aimed at destabilizing the epistemological belief that scientists had special access—through the application of the proper use of the scientific method, empirical observation aimed at development of theory, and so on—to underlying and unquestionable truths. Conceiving of science as a social practice and building on the discipline of the history and philosophy of science, practitioners in the sociology

of scientific knowledge (SSK) sought to unravel the ways in which scientific “fact” and theory emerge out of various and multiple social processes. Rather than assume an a priori objectivity, in which scientific knowledge is presented as a mirror of external reality (i.e., nature), SSK developed a method and approach in which all knowledge claims were to be examined with equivalent and symmetrical skepticism and where the object of inquiry was to examine the conditions under which claims to knowledge came to be seen as legitimate and true. A “strong program” developed committed to a relativist and empirical program aimed at studying the microsocial dynamics of science through which scientific reality came to be socially constructed through laboratory study and experiment.

Perhaps not surprisingly, such an overt attack on the authority of science led to a concerted counterattack from many in the scientific establishment who tended to criticize such interventions as unjustified, premised on faulty logic, sloppy in scholarship, and even politically motivated. The so-called science wars, between “postmodernists” or social constructivists on one side and scientific realists on the other, raged especially throughout the 1990s in several largely unproductive and often acrimonious exchanges. One highly published event was the “Sokal affair,” arising from a paper written by the physicist Alan Sokal purportedly to argue that quantum physics supported constructivist criticisms of the objectivity of science. Following publication in the journal *Social Text*, Sokal revealed the paper to be a hoax and cited the publication as demonstrable evidence of the poor standards and dogma that existed in postmodernist circles.

The field known as “science studies” extended its gaze to embrace the “technological” through a series of formative books in the 1980s. Arguing against technological determinism—the belief that technologies follow their own developmental path and trajectory, outside human influences—this body of work sought to highlight the human choices and values that are embedded in technological design, that constrain or enable innovation pathways, and that open the “black box” of technology to allow the socioeconomic patterns embedded in innovation processes to be exposed and analyzed.

Phase 2: From Epistemology to Politics and Public Engagement

Throughout the 1980s, a body of scholarship developed, concerned less with “internalist” matters of epistemology and scientific truth and more with “externalist” matters concerning the use of scientific knowledge in “live” public arenas and the potential for wider public involvement in scientific and technical decision making. This more overtly political variant of STS, with a normative commitment to social change, arose out of a dynamic interplay between SSK, controversy studies, legal scholarship, and risk theory. The analysis of public controversy proved to be a fertile ground for STS scholarship.

Brian Wynne was a formative influence as a scholar who sought to mobilize STS insight to assist wider recognition of marginal voices and conflicting framings of the scope and meaning of controversial issues. Analyzing the controversy over the proposed nuclear power–reprocessing plant THORP at the 1977 Windscale public inquiry in the United Kingdom, Wynne realized that the argument between the objectors and the protagonists was ostensibly one of framing: Whereas the official and expert-derived terms of reference related to the risks and implications of this plant alone, for the objectors the issue concerned the wider consequences of its construction, including the use of reprocessed plutonium for future bombs and the transport of spent fuel and other dangerous materials in the so-called plutonium economy. Without taking an explicit stance, Wynne argued (unsuccessfully) for a wider debate as to the extent to which the public inquiry should deliberate on these wider responsibilities. A similar account was provided of the North Sea Brent Spar oil platform controversy, analyzed by STS scholars as a conflict over the framing of what constitutes the salient issue. For Royal Dutch Shell and the U.K. government, the salient issue concerned the risks posed by the dumping of a single oil platform in the deep Atlantic Ocean, while for Greenpeace and other objectors, the core issue concerned the precedent the dumping would provide for disposing of all kinds of wastes, including radioactive waste. Furthermore, STS insight was brought to bear on, *inter alia*, the importance of framing to issues as

diverse as the bovine spongiform encephalopathy (BSE) mad cow controversy, the human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS), genetically modified (GM) foods and crops, xenotransplantation, nature conservation and wildlife, the addition of fluoride to public water supplies to prevent tooth decay, and intelligent design.

Of key concern across the above case studies was the way in which expert and scientific communities defined, established, and maintained official definitions of what is salient and what is erased from public attention. The politics of research was one of critical engagement with expert policy framings of significant public issues—themselves often reinforced by reductionist processes of scientific risk assessment—where the normative task was one of making public and other marginalized knowledge claims available to expert groups. A tradition of policy-oriented academic research emerged that used small groups as a deliberative space where lay publics could share their experiences, values, and knowledge and where STS scholars could bring recognition of such local knowledge in the quest of making decision making more socially robust.

Interestingly, and following a series of acute and politically damaging technological risk controversies (notably in the United Kingdom and Europe around BSE and GM foods), such scholarship contributed toward a more explicitly deliberative turn in technological governance. Whereas earlier technological decision-making processes had been grounded in notions of “sound science” and expert advice, where public opposition to technological innovation was represented as due to faulty and unreasonable logic, the new governance regime was more conciliatory to different kinds of knowledge claims, and the institutional task was to open up decision-making processes through dialogue with publics and other stakeholders. A series of influential reports were written, all calling for more proactive public involvement and deliberation in debates about the social and ethical dimensions of science and technology. In the United Kingdom, these included the formative 3rd report by the House of Lords Select Committee on Science and Technology, *Science and Society* (2000), and the 21st report by the Royal Commission of Environmental Pollution,

Setting Standards (1998), while in Europe this new deliberative move was captured in a series of reports and action plans on science and society. And indeed, in recent years, a range of policy institutions have attempted to democratize aspects of their decision-making processes through assorted participatory mechanisms that include consensus conferences, deliberative polling, citizen juries, citizen panels, and focus groups.

Several core intellectual resources have been developed to assist and structure STS inquiry. These include the concept of “coproduction,” an idea developed by Sheila Jasanoff and colleagues to examine the dynamics through which science and social orders become mutually constituted; the idea of “civic epistemology,” again pioneered by Jasanoff to refer to the culturally specific practices of knowledge production that characterize public life and civic institutions and that are used as a basis for making collective choices; and the approach of “actor network theory,” developed by Michel Callon and Bruno Latour as a method for analyzing the relationship between things, ideas, people, and technologies, both as actors and as networks.

Phase 3: Critical Debates

In more recent years, a series of debates have been taking place within STS, concerning its relationship to institutional practice, to expertise, and to innovation research and development. The first concerns the development of a more critical and reflexive relationship between STS and institutional models and approaches to public engagement. Whereas STS had previously tended to advocate public participation and citizen engagement in science as an *a priori* good, an emerging body of scholarship is proposing a more analytically skeptical approach, asking whether and under what conditions public participation can deliver its promised benefits, such as enhanced public trust, more socially robust decisions, and a better understanding of scientific and technological risk issues. Harry Collins, Robert Evans, and colleagues have initiated a conversation on the need to distinguish between different kinds of expertise and between different types of publics or lay citizens and on the need for more critical scrutiny of the ways in which public deliberation

is being used in science-based policy making. Alan Irwin, for example, has analyzed the ambivalence that exists within policy institutions, which have embraced public dialogue and transparency on the one hand while sustaining a professional and expert-derived “risk and consequences” framework on the other.

Brian Wynne has criticized institutional public engagement activity for its emphasis on “downstream” questions of risk and harm, calling instead for public deliberation to be directed “upstream,” to the scientific visions and “imaginaries” that are shaping the purposes and trajectories of scientific and technological research. This attempt to provide a more substantive role for STS in scientific and technological innovation has been developed into programs of research in the Netherlands, what is termed *constructive technology assessment*, and in the United States, called *real-time technology assessment*. Both attempt to provide a method in which relevant actors, including publics, are brought together in a process that aims to inform and shape innovation and decision-making practices.

SCOTT, ALLEN (1938–)

One of economic and urban geography's most influential contemporary figures, Allen J. Scott introduced some of the fundamental concepts of contemporary urban political economy, including industrial organization and change and, more recently, the cultural economies of cities.

British in origin, he attended Oxford University, completing his BA in 1961 and MA in 1965. He earned his PhD at Northwestern University in 1965. He taught for several years at the University of Toronto before moving to the University of California, Los Angeles (UCLA) in 1981, where he has since remained as a professor of geography and public policy. He has written 10 single-authored books and coedited 9 more, as well as numerous journal articles; has served as visiting lecturer in various locales; and is the recipient of numerous awards, prizes, honors, and distinguished fellowships.

While Scott's training and early work lay in the domain of mathematical modeling, including location-allocation analysis, the bulk of his contributions lay in dissecting the space economy of metropolitan regions. Specifically, he articulated views of cities as changing systems of production, incorporating older Marxist ideas of the division of labor in novel and intriguing ways. In reviving the older tradition of transactions costs analysis, he was instrumental in sketching the contours of industrial restructuring in the form of the rise of flexible production and accumulation (or "post-Fordism") in the 1980s. His projects stressed the powerful role played by corporate vertical integration and disintegration in reshaping urban

labor markets and spaces, including the rise of "new industrial spaces" distinct from the traditional spatialities of Fordism. Thus, the importance of agglomeration economies fluctuates over time depending on the predominant system of subcontracting, the degree of risk involved, and other factors that reshape the input-output relations among firms. In fusing circuits of commodity production and social reproduction, Scott revealed how the changing division of labor spins off various dimensions in the labor market, such as job gains and losses and the presence or absence of particular complexes of occupations, technologies, and spatial differences in skill sets. Concomitantly, such changes led to associated social geographies, as exemplified by urban gentrification on the one hand and low-income, working-class ghettos on the other. Scott's efforts also helped discredit neoclassical economic myth of a "free market" by pointing out the inevitable role of the state and urban planning in rationalizing urban land use predicaments. His views thus provided a theoretically powerful, integrated synthesis of longstanding but undersocialized notions in geography such as input-output analysis, the product cycle, agglomeration economies, transactions costs, the geography of labor, state intervention, and technological change.

Scott brought these notions to bear on the specific case of Southern California through a series of detailed case studies on the aerospace, the electronics, and particularly the film industry, among others, thus becoming one of the informal founders of the influential so-called Los Angeles School of urban and regional analysis.

His works on Southern California became widely influential in the revival of regional analysis in geography in the late 20th century, a view that positioned local production complexes within wider national and global divisions of labor. Situating regions within worldwide commodity chains led to an informative fusion of the global and local in the analysis of particular places. Scott extended such analysis from iconic regions such as Silicon Valley and Italy's Emilia-Romagna to dense complexes of service firms at the core of large urban regions found worldwide.

More recently, given the cultural turn within economic geography, Scott has emphasized the powerful constitutive role of cultural industries

such as the Hollywood film complex. Specifically, the interiors of many large urban spaces have become transformed into spaces for the production of symbolic and cognitive capital—locales of leisure for the legions of workers employed in such industries and centers for the creation of taste, images, style, and fashion—and other dimensions of representational and informational commodities.

Scott also offered powerful and elegant critiques and analytical histories of geographic thought and epistemology, emphasizing the social origins and contexts of discourses within the discipline rather than the common view of ideas as self-propelled abstractions devoid of material foundations.

SEDIMENTARY ROCK

Sediments are loose, unconsolidated rock particles and ions (i.e., charged atoms) dissolved in aqueous solutions. Sedimentary rocks, which constitute about 75% of all rocks exposed at the surface of the Earth, form when the particles are cemented together or when crystals precipitate from the solutions. Sedimentary rocks (particularly sandstones) are important because they host petroleum deposits and most of the uranium used for generating nuclear energy. There are three types of sedimentary rocks: (1) clastic (or detrital), (2) biochemical, and (3) chemical.

Clastic sedimentary rocks constitute more than 75% of the total sedimentary rocks. These rocks are formed from cemented grains and particles derived from the breakdown of preexisting rocks of any type (e.g., igneous, sedimentary, or metamorphic). The classification of clastic sedimentary rocks is based mainly on the size of the grains. A clastic sedimentary rock formed by gravel (i.e., grains bigger than 2 mm [millimeters] in diameter: granules, pebbles, or boulders) is called conglomerate (if the grains are rounded) or breccia (if the grains are angular). A clastic sedimentary rock formed by grains between 1/16 and 2 mm in diameter is called sandstone. Sandstones can be further classified according to the most abundant minerals they contain. Sandstones formed mostly

Colorful sedimentary layers in a road cut at Artist's Point in the Colorado National Monument near Grand Junction

Source: Linda Armstrong/iStockphoto.

by grains of the mineral quartz are called quartz sandstones (or quartz arenites), whereas sandstones formed mostly by grains of the mineral feldspar are called arkoses. Sandstones that include high amounts of fine-grained clay are called graywackes. Conglomerates, breccias, and sandstones are formed by grains that are coarse enough to be seen with the naked eye. In contrast, grains of silt (between 1/256 and 1/16 mm in diameter) and clay (smaller than 1/256 mm in diameter) are too small to be seen with the naked eye. Silt and clay grains, when cemented together, form the clastic rocks siltstones and claystones, respectively. Siltstones and claystones are sometimes collectively called mudstones. A mudstone that easily splits in different layers is a shale.

Biochemical sedimentary rocks are formed from the remains of organisms. Peat and bituminous coal are formed from plant fragments. Peat is commonly brown and porous, with plant fragments that are still visible. In contrast, bituminous coal is black without distinguishable plant remains. Fossiliferous limestone is formed from fossil shells and coral and is the most common biochemical sedimentary rock.

Sedimentary rocks belonging to the last type (chemical) form by precipitation from aqueous solutions. These rocks are classified according to their chemical composition. Some common chemical sedimentary rocks are limestone (formed by CaCO_3), dolostone ($\text{CaMg}(\text{CO}_3)_2$), chert (SiO_2), rock salt (NaCl), and rock gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$). Limestone is the rock that most commonly is responsible for the development of karst topography.

SEDIMENTATION

Sedimentation involves the response of motion of molecules or particles to gravitational, centrifugal, or electrochemical forces. Sedimentation literally means the manner in which a sediment is taken out of whatever transportation process it is dissolved or entrained in (water, wind, gravity, waves, etc.), resulting in a deposit of sediment. Thus, sedimentation can occur naturally from the

various fluids or the media of movement, or it can occur artificially in different human environments (e.g., inside a laboratory vessel or water and wastewater treatment plants). The net result is that material is removed from further direct interaction with its entraining agent and is generally blocked by a hard boundary against which it is then lodged. This then constitutes a new collection of sediments. Many different genetic forms of sedimentation can result, but only those of the natural world are considered in this entry.

Sedimentation resulting from cessation of gravity-induced motion without significant entrainment by fluids includes the many forms of mass movement or landslides as well as the results of subsidence, or isolated motions of creep, talus accumulation, rock glaciers, and other such forms. Both mass movement and subsidence result in accumulations of mixed up, unsorted, unstratified

clastics and organics in colluvium. Glacier ice also moves downhill under the influence of gravity, which is similarly unsorted and unstratified, although these deposits commonly have grain-surface characteristics that enable differentiation from colluvium.

The motion of air and water can entrain vast quantities of clastics and organics as well as dissolved solute loads. With both fluids, once the velocity of the transporting medium drops below a certain amount required to keep the load in motion, sedimentation occurs and deposition results, commonly sorted into different forms such as clay, silt, sand, and various sizes of gravel and boulders. Sedimentation of sand from wind results in dunes, which can be easily remobilized once the wind picks up again. On the other hand, once the sedimentation of silt and clay dust occurs, the small particles are not easily entrained

again, resulting in loess blankets across the landscape. Water, unlike wind, has the capacity to dissolve some rock, as well as move many different grain sizes, depending on the velocity. As with wind, the clastic load undergoes sedimentation as the velocity decreases so that bars and deltas, beaches, lakebeds, and alluvial fans all result in deposits of sorted and stratified alluvium. Where water evaporates, the solute load comes out of the solution and produces the sedimentation of salt flats or the dripping deposition of stalactites and stalagmites in caves. One unusual form of sedimentation from solution involves the precipitation of pure silica (SiO_2), which when it occurs in layers commonly colored by iron forms semi-precious agates and other kinds of colorful silica compounds that are quite durable. When, however, the silica is precipitated in a very regular fashion, where the individual silica molecules are lined up very precisely in rows covered with clear silica, the new sediment can separate light like a refraction grating to produce iridescent opals.

SEGREGATION AND GEOGRAPHY

Segregation derives from the Latin verb “to separate” or “to divide,” and in the social sciences, it defines the separation of a group of people from the rest of the population. Segregation does not have to be a particularly geographical phenomenon—it can involve any manner of separation—but it often takes geographical forms and is most apparent in cities where the social patterns of people are distinct. The study of segregation has become

an important topic in human geography. It also lends itself well to the tool kits of geography, from maps to spatial statistics to ethnography. Geographers have discussed segregation in several ways: from helping describe it, to revealing the processes that cause it, to an understanding of what segregation means to those who experience it.

Any group of people can be segregated, and these patterns are apparent in the city. Segregation on the basis of income defines the broad social areas in cities, with neighborhoods divided between low, middle, and higher incomes. Segregation on the basis of life cycle considers the tendency of neighborhoods to be dominated by people at certain stages of their lives, from young adult singles to families with children, to empty nesters and elderly enclaves. There may also be segregation based on lifestyle, as arts-oriented individuals congregate in neighborhoods more suited to their tastes. However, it is on the basis of race and ethnicity that segregation is most often discussed. In diverse cities—which describe most cities—different cultural groups are more or less likely to cluster together. This creates an uneven geography as certain groups may be found in specific parts of the city and almost absent from other districts. Social scientists are more concerned with this sort of segregation because it seems to be less voluntary than the other forms, indicates profound social tensions, or stems from discrimination.

Measures of Segregation

Thematic maps that display the density or proportional representation of particular groups provide a good depiction of how segregation appears. While maps illustrate the stark patterns and divisions between groups, it can be useful to develop more precise measurements. Both sociologists and geographers helped popularize a simple measure of segregation known as the *index of dissimilarity*, or *D*. The *D* index ranges from 0, which indicates that a particular subgroup is evenly dispersed throughout the entire population of a city, to 100 (or 1.0), which indicates complete segregation. With this index and a few others that are calculated in slightly different ways, it is possible to compare the segregation levels of different groups,

examine segregation in different cities, or trace the segregation experiences of a group over time. Segregation indices have played a profound role in characterizing the experiences of ethnic and racial groups in cities around the world and have had a powerful effect in shaping public policy.

Traditional segregation measures used census units and were impervious to the geographical relationships between those units. In other words, this information could not account for whether African Americans, say, were concentrated in one census tract but were absent in an adjacent one. New geographic technologies have allowed researchers to modify segregation indices to measure the spatial relationships between units and to offer a more refined measurement.

It is more problematic that such measures are prisoners of the categories provided by official government agencies and so are only as good as the data derived. Many governments choose not to report data by certain categories. For instance, the U.S. Census does not provide information on religious affiliation, whereas Statistics Canada does provide this information. The clustering of ethnic North Africans in French cities, for example, is of social concern. Recently, there has been a spate of riots in the suburbs, where many North African ethnics live in relatively impoverished conditions. But the French statistical service (INSEE) does not report information on different ethnic, religious, or nationality categories at a small enough scale to permit useful analysis.

Types of Segregation

Segregation stems from many different causes, and these help determine the nature of the segregation experience. One distinction can be made regarding so-called *de jure* segregation, in which the separation and concentration of a particular group is mandated by law. Historically, societies could require that members of a particular group occupy a single district or a ghetto. South Africa's former apartheid regime enforced *de jure* segregation through the Group Areas Act.

Most cities today are more likely to experience *de facto* segregation, which means that segregation exists but is not legally mandated. Depending on the groups and the contexts involved, much of this segregation derives from negative

factors. Often, segregation is bound up with socioeconomic status. Many minority populations are also poor and so are disproportionately represented in the poorest districts of the city. In North America, segregation was also caused by overt discrimination, whereby banks, realtors, property owners, and others compelled individuals of a particular ethnicity or race to live in some places by restricting their access to other areas. Immigrants who arrived in the late 19th and early 20th centuries experienced such discrimination, and it was particularly pronounced against some groups, such as the Chinese population on the Pacific coast of the United States. With the urbanization of African Americans in the 20th century, this level of overt discrimination reached an extreme as a variety of mechanisms, including property covenants and housing discrimination, enforced strict patterns of black residential segregation. While most such mechanisms have been overturned, many scholars believe that there still exist a number of more subtle discriminatory practices as well as a legacy that continues to keep African American segregation patterns high, regardless of socioeconomic standing.

Reasons for Segregation

Members of an ethnic group may themselves have reasons to segregate, even if they are not subject to discrimination or socioeconomic constraints. Such "preferences" can stem from varying motives. For some groups, segregation provides protection from other, hostile groups. In politically tense cities such as Belfast, Beirut, Baghdad, and Sarajevo, groups will form virtual fortresses from neighborhoods, complete with walls and security patrols. A more benign form is where a group seeks to segregate as a type of cultural defense. English speakers in Montreal cluster as a way to retain their culture within an increasingly French city. Many groups may segregate to be close to religious institutions; for example, many Orthodox Jewish populations cluster within walking distance of the synagogue. Finally, segregation may be viewed as an outcome where people choose to live close to people like themselves. Surveys have indicated that proximity to similar people makes residents more comfortable, although groups vary in their tolerance for neighborhood diversity. Such

Loyalists march past one of the Peace Lines separating Catholic and Protestant neighborhoods in Belfast on their way to Belfast Town Hall, November 23, 1985. They were protesting against the previous week's signing of the Anglo-Irish Agreement between the United Kingdom and Ireland, which gave the Irish government an advisory role in Northern Ireland's government.

preferences are a double-edged sword, of course, since one group's preference for its own kind effectively excludes other groups from living nearby.

Consequences of Segregation

The consequences of segregation vary and are partly related to whether the segregation results from constraint or choice. Many groups that are forced to occupy particular neighborhoods suffer from this enforced segregation. Such patterns have been linked to diminished accessibility to jobs, shopping, and banks and to higher levels of poverty and social dislocation. It is because of these ill effects that public policy has endeavored to diminish segregation.

More positive outcomes can result when segregation is a matter of choice. The clustering of

members of the same ethnic group often provides the thresholds necessary to support a variety of institutions, including religious ones. But larger concentrations of ethnics can also sustain specialty grocery stores, services geared toward ethnic needs, and sometimes even ethnic banks. Entire ethnic economies can benefit from such proximity. What is more, concentration of ethnics allows for greater political influence as they have the necessary votes to send one of their own to the regional or national legislature. Ethnic majorities can elect the government for a city or town. For instance, Cuban Americans have marshaled tremendous political potency by virtue of their concentration in the Miami metropolitan area. Even when segregation is not a matter of choice, sometimes disadvantaged groups can wring some advantage from it.

A large component of what makes human geography interesting is the examination of patterns. The segregation of particular ethnic groups is a fundamental pattern in most cities that results from many factors that lead people to cluster in groups and live apart from other groups. Such segregated patterns can also have major consequences for all residents of the city and become a determining factor in modern urban life.

attributes rather than a space of geographic coordinates. Methodologically, SOM computation relates to the suite of multidimensional scaling (MDS) methods (e.g., principal components analysis [PCA], factor analysis, *K* nearest-neighbor method, and many others) that attempt to project multidimensional variables to limited dimensional (often 2D and 3D) spaces, so that humans can discern meaningful patterns through visualization and analysis. More specifically, Teuvo Kohonen, the inventor of SOM, suggested that SOM is an ordered structure of “local PCA” in that the non-linearity of data vectors precludes the appropriateness of common principal components to explain all data vectors. Instead, an SOM presents 2D grouping of data vectors, and the first and second principal components vary from one group to another over the SOM.

Compared with many MDS methods, SOM method is fundamentally a nonparametric regression approach with neural network learning algorithms. SOM handles each data item as a vector of values in an ordered array of variables. An SOM is built by a sequence of iterative processes:

1. Determining the topological structure of neighborhoods
2. Determining the first set of reference vectors (usually random or based on known structures in the data)
3. Calculating the distances of individual data vectors to reference vectors and determine first grouping
4. Calculating the next generation of reference vectors based on a mathematical definition of “generalized median” vectors from the defined neighborhood of the previous grouping
5. Reiterating the steps until the reference vectors converge into a predefined structure

Neighborhoods of hexagons are preferred over squares because hexagons show the same range from the center to all sides. As an SOM is built through iterative learning processes in the determination of reference vectors and grouping, the size of the neighborhood and the number of iterations can influence the learning factor and degree of convergence in the final map. Kohonen recommended that the neighborhood size start at

SELF-ORGANIZING MAPS

Self-organizing maps (SOMs) are not cartographic maps; rather SOMs are mathematical transformations of data to a predefined two-dimensional (2D) structure to reveal data clusters based on similarity. Conceptually, the basic idea of SOM corresponds well to Tobler’s first law of geography, but SOMs consider distances in a space of multiple

half the diameter of the network (i.e., the defined size of the SOM, analogous to spatial extent), reducing over time during the computation to perhaps the cell unit in the end of the computation. Furthermore, according to Kohonen's rule of thumb, the number of iterations should be at least 500 times the number of network units (i.e., the defined size of the SOM cell unit, analogous to resolution) to ensure good statistical accuracy; a typical number of iterations used in building SOM is 100,000.

How to measure distance is central to determining similarity among data items and, therefore, SOM outcomes. There are several ways to measure distance; Euclidean distance (simple linear distance between two points), Hamming distance (the number of steps to make two binary lists identical), Levenshtein distance (the total number of required steps—replacements, insertions, and deletion—to make two strings identical), or simply binary distance (0 or 1) are commonly used distance metrics. Because the distance measures will be computed in a vector space with variables that may have distinct value domains, standardization of variables is critical to avoid variables with high values overpowering other variables and dominating the computation of distance. Often, variables are standardized based on statistical parameters (such as means and standard deviation) or other means appropriate for the data on hand.

SOM has been expanded with complexity, such as hierarchical SOM or latent semantic indexing SOM. Of most interest to geographers is GeoSOM, which adds geographic coordinates into the attribute vectors, so that the resultant SOM accounts for groupings in both attribute space and geographic space. Consequently, GeoSOM shows that interpretation of clusters can be spatially dependent; that is, the first and second principal components that can best explain clusters vary across geographic space. For example, social clusters in the northern part of a city may be mostly employment related, and clusters in the southern part of the city may be strongly correlated with household income.

Applications

SOM has been used broadly in many domain applications since 1981. Many SOM applications

developed from the late 1990s are related to geographic studies. SOM has been used to investigate extreme climate events, regional precipitation patterns, and distributions of nonnative species. SOM has also been used for image processing, solving location-allocation problems, comparison of cities, integrated environmental assessment, visualizing demographic trajectories, comparing community health, and many more. The wide range of applications demonstrates SOM's capabilities to reveal hidden data orders for visual analysis. Cartographers with an interest in visualization consider SOM as one of the spatialization methods that can transform nongeographic data into spatial representation. As geographers dig into nonlinear, complex geographic systems, SOM can become one of the key tools to simplify complexity by reducing data dimensions yet discerning the fundamental data orders to facilitate interpretation.

(SOA) describes the interaction among the service provider, the service broker, and the user. The provider registers the service at a registry maintained by the service broker. The broker publishes the service interface and, hence, allows the service to be retrieved and finally executed by the user. The interface describes how to access the service and which data, if any, are exchanged. Besides human users, other services can also request a service via its interface, forming service chains. The interface description guarantees syntactic interoperability, that is, the possibility to exchange data on a technical level. Besides the used Internet protocol and access restrictions, this especially includes the used data types. For instance, an interface of a Web-based gazetteer may announce that it requires a place name as input and delivers the place type and spatial footprint as results. The place name and place type would be specified as text strings, while the footprint would be defined according to a particular spatial reference system. What a place type (such as a lake or canal) means, that is, what is required for a particular place to be classified as a lake or canal, is not covered by the interface description. This is a serious shortcoming as users accessing the service may assume that the services' conceptualization of the place type fits their own. Consequently, relying only on the names and data types of service parameters is not sufficient. This is especially important for service chains where one service relies on the adequate output of another service without manual control by a human user.

In contrast, to avoid misunderstandings, semantic interoperability requires a shared understanding of the meaning of the exchanged data, such as the place types in the gazetteer example. To achieve this, unambiguous specifications of the service functionality as well as the meaning of the input and output parameters are necessary. These specifications have to be readable to both human users and machines and also have to be published in a service registry to support discovery. With respect to the gazetteer, the service needs to provide the specifications for the place types. For instance, lakes can be defined as natural bodies of water inside a landmass. Based on such definitions, users (or other services) can decide whether the requested service fits their requirements. In information science, the technology to specify such conceptualization is called an *ontology*. Ontologies support

SEMANTIC INTEROPERABILITY

With geographic information systems (GIS) moving away from monolithic software to distributed network services, the question of how to ensure that these services operate with each other gains in importance. Typically, these services encapsulate a particular functionality exposed through a Web-based interface for communication as proposed by the Open Geospatial Consortium (OGC). The service-oriented architecture

logical reasoning, which is a prerequisite for information retrieval and interpretation. To achieve semantic interoperability between services, their ontologies, called application ontologies, are compared to analyze whether the service parameters are based on the same conceptualization. Such an analysis, however, requires a common base vocabulary used for the specifications.

An analogy to explain the need for a base vocabulary and the comparison of conceptualizations in application ontologies are semantic reference systems (SRS). Like spatial reference systems, SRS defines a multidimensional (semantic) coordinate system and operations within such a system. One of these operations is semantic similarity, which is defined as the inverse distance between two conceptualizations. It is analogous to the distance between coordinates in a spatial reference system. Consequently, while the distance between two places represented in a gazetteer service can be measured based on their spatial footprints, the semantic similarity of the place types can be computed based on their formal specifications. While the question of how to achieve semantic interoperability remains an open research challenge, two approaches can be distinguished.

Top-Level Ontology

A top-level ontology contains the commonly agreed on base vocabulary independent of an application-specific perspective, for example, a particular service. For instance, a top-level ontology distinguishes between abstract and physical objects and defines units of measure. These specifications are then used as building blocks for domain ontologies, which specify the vocabulary shared by a particular domain such as hydrology or geography. The domain ontology itself is used by the service provider to develop the application-centric ontology necessary for the service interface. In case of the gazetteer service, the provider specifies what is categorized as a lake, using definitions from the domain ontology, such as the topological inside relationship or the concept of water body. The mathematical notion of a relationship is defined in the top-level ontology. Based on this top-down approach, the specifications used by particular services can be compared as they rely on the same base vocabulary. This also

allows for computer-aided search in service repositories and enables users to find the services that fit their needs. Semantic similarity is such a technology to support retrieval based on comparing the specifications for overlap and is a step toward establishing semantic interoperability.

Folksonomies

While the definition and maintenance of top-level and domain ontologies are up to computer scientists and domain experts, so-called folksonomies are a bottom-up approach to establish a common understanding of the used vocabulary. Folksonomies are a crucial part of the Web 2.0, where users actively contribute content instead of passively consuming it. By assigning labels (tags), users categorize content on the Web. For instance, in a Web 2.0 gazetteer, users might assign tags as place types to mark particular places on a map. Technologies to analyze these tags and hence establish a common understanding based on user-provided information are a promising new research direction.

SEMANTIC REFERENCE SYSTEMS

Geographic information systems (GIS) operate on spatial, temporal, and thematic data. The interpretation of the first two kinds of data is given by well-known spatial and temporal reference systems

such as coordinate systems and calendars. Based on these reference systems, we can transform between coordinates and time stamps or measure distance in space and time. We can also project three-dimensional coordinates into two-dimensional representations for paper maps. What is needed is a reference system for the third kind of data. In analogy to spatial and temporal reference systems, semantic reference systems (SRS) allow the transformation and projection of thematic data or the calculation of semantic distance (called semantic similarity). Typical applications for such an SRS include the transformation or comparison of different conceptualizations between information communities, and information retrieval in general. In the first case, this would allow mediation between the conceptualization of water bodies as used in hydrology and the one used in tourism. In the second case, one could retrieve similar water bodies or kinds of water bodies (such as a lake, river, or reservoir) based on a user's query. An SRS consists of two parts: (1) the semantic reference frame, that is, a formal system such as an ontology, and (2) particular semantic datums to ground the meaning of the terms used in the reference frame.

Ontologies as Reference Frames

An ontology specifies the conceptualization of a particular information community by providing formal definitions for the terms used in this community. To do so, ontologies need to introduce primitive terms for the definition of more complex ones. For instance, the term *river* could be specified by introducing the term *spring* and the relation *has_origin* between rivers and springs. One could also define attributes, such as *flow_velocity* and *water_gauge*, and introduce kinds of rivers, such as *forest_river*. In turn, we also have to specify the meaning of terms such as *spring* and also the attributes and relations used to specify the meaning of *river*. We continue with the specification process until only primitives are left, that is, terms, relation, and attributes for which no formal definition can be given within our ontology. To ensure consistency in the interpretation of these terms, and hence to achieve semantic interoperability, we need to ground these primitives in observable reality by introducing semantic datums.

Summing up, ontologies restrict the potential meanings of terms used in an information community. However, to restrict the possible interpretations exactly to the intended ones, a semantic datum is needed. Besides specifying a vocabulary, ontologies support logical reasoning, which is a prerequisite for information retrieval. For instance, if we define particular attributes such as *flow_velocity* for *river*, we can infer that each water body that has been classified as a river has a flow velocity. Semantics-aware search engines use reasoning to deliver more flexible results. If a user types in *stream* as a keyword, the search engine would also include kinds of streams, such as rivers and creeks, and also similar water bodies (such as reservoirs if the user is querying for *lake*) in the result set.

Semantic Datums and Sensors

A semantic datum provides a particular interpretation for the primitives of a frame of reference to something outside it. An interpretation is a function from all symbols (terms, attributes, and relations) in an ontology to some particular other structure that preserves the truth of its sentences. Typically, an ontology allows for more than one interpretation that satisfies its sentences, and therefore it has an ambiguous meaning. As all nonprimitive symbols in an ontology are definable from the primitive ones, a semantic datum can fix one particular interpretation. The structure in which the symbols are interpreted can be other ontologies as well as observable real-world structures. We say that an ontology is grounded if there exists a semantic datum for an interpretation into observable real-world structures. Examples of interpretations into observable real-world structures are measurement scales. This can be illustrated by the analogy to spatial reference systems. Spatial reference frames are grounded. A datum in a spatial reference frame fixes the position of the origin, the orientation of coordinate axes of the reference frame relative to Earth, and the length measurement scale that fixes the units of measurement. All coordinates and their relative locations are defined in origins and units of such a reference frame.

There are two ways of establishing a semantic datum for a semantic reference frame. First, there is a physical sensor available that grounds primitive symbols directly into observable real-world

structures. A sensor can be considered as a physical device that implements such an interpretation. In our example, a directly observable semantic datum for the Bessel ellipsoid is, for instance, a named spot on the Earth's surface, such as "Rauenberg" near Berlin (Potsdam Datum). Second, there is a criterion available to define the primitive in a second reference frame. The point of origin and the units of a map projection, such as a Gauss-Krüger strip, are, for instance, definable from a reference ellipsoid, such as Bessel. In terms of the water body example, a river's gauge is defined with reference to its bankfull stage (as datum). The bankfull stage is the level of the water surface measured when the river's banks are under water. The level of water surface in turn is the vertical distance measured between the idealized water body surface to the air and the idealized surface to the river bed.

SEMPLE, ELLEN CHURCHILL (1863–1932)

Born in Kentucky in 1863, Ellen Churchill Semple was a leading American geographer of the early 20th century and a pioneering female geographer. She was a charter member of the Association of American Geographers in 1904 and became the

first female president of an academic organization in 1921.

Semple received her bachelor's degree from Vassar College in 1882 and a master's degree in 1891. In the 1890s, Semple studied at the University of Leipzig in Germany under the world's most prominent human geographer, Friedrich Ratzel. Due to the prevailing sexual discrimination at the time, Semple could not enroll in the doctoral program at Leipzig while studying with Ratzel and was even required to sit apart from her male colleagues (she would face discrimination throughout her career, for example, as a faculty member earning a lower salary than her male counterparts).

During her academic career, Semple published three major books and numerous journal articles. Her first book, *American History and Its Geographic Condition*, was published in 1903. Three years later, in 1906, she accepted an appointment in the University of Chicago's geography department. In 1921, she moved to Clark University, where she accepted a position as professor of anthropogeography. Semple suffered a heart attack in 1929 and died 3 years later in Florida around the time of publication of her last major book, *The Geography of the Mediterranean Region*. Semple was a major intellectual force in American geography in the early 20th century, and her influence through her work and graduate students continued for decades afterward.

Semple is best known for her 1911 book, *Influences of Geographic Environment on the Basis of Ratzel's System of Anthro-Geography*, in which she introduced and reinterpreted her mentor's ideas to American geographers. In this and other works, Semple attempted to demonstrate the benefits of the scientific study of human geography. However, she did this through her role as a leading American proponent of the, long since discredited, theory of environmental determinism, for which she is most remembered today. Semple argued that the environmental conditions under which humans were born, were raised, and lived, and in which their societies developed over time, played a major role in shaping intelligence, temperament, and culture (indeed, Semple's 600-page tome begins with the statement, "Man [*sic*] is a product of the earth's surface"). Through her formulations of environmental determinism,

Semple came to dubious conclusions, from assuming that people living in mountain passes were more likely to be bandits to associating world climate types with distinctive human characteristics. The latter led to racist conclusions linking climate and “race temperament,” with Northern Europeans being “energetic” and “thoughtful,” Southern Europeans being “easygoing” and “emotional,” and positive characteristics giving way to “grave racial faults” among black Africans. While she was not alone in holding these beliefs, Semple’s work on and ideas about environmental determinism had a major impact on the shaping of American geography in the 1910s and 1920s.

Among myriad approaches to sense of place, a key strand begins with the individual. Each person brings his or her own personality, background, and previous experiences into the process of forming a sense of place. People draw on their own use of the human senses, their own sense of aesthetics, and their own intellectual and emotional responses that they have developed with regard to places; these are based on their experiences and perceptions and the development of cognitive understandings of places. One’s reactions and responses are not static, however, and the way one looks at places continues to evolve as one’s life cycle develops and as the landscapes and places around one are transformed. Through those processes, it can be argued that people develop (at varying levels of sophistication) their own landscapes of memory and previous experiences. In some cases, this leads to bonding with places—love of place—while in others, it can lead to ambivalence, disinterest, and/or rejection, that is, the placelessness of interchangeable superficial identities that can be found anywhere. Furthermore, in invoking sense of place, many humanistic geographers and others from the humanities are attempting to understand the nonreductionist uniqueness of individual responses, as well as the distinctiveness that different places possess, and to open the minds of people to the richness of the world through place-based approaches and, specifically, to think about the role that places play in their lives.

Many individuals share a sense of place with others in a subgroup or across broader social and cultural lines. Within other social and behavioral sciences, and for some geographers as well, there are attempts to understand the psychological aspects of a subgroup’s perceptual and behavioral approaches to sense of place. Some group studies of places have been conducted in the humanities and by the cultural landscape school of geography, and they usually involve historically tracing an understanding of places at local and regional levels or through folklore and hand-me-down stories.

In contrast, other geographers and some space/environment disciplines tend to look more at the role specific places play in that process, including studying the character of places themselves and why particular places evoke a sense of

SENSE OF PLACE

Sense of place refers to subjective human reactions to places. With roots in early forms of humanistic geography, the concept appears in various forms in a considerable body of works expanding on human experience, memory, imagination, emotion, and meaning; accordingly, it is a core value in a broad and varied range of endeavors from theory (i.e., placing humans in Earth’s time-space continuum) to practice (e.g., building “green” or selling places as commodities). In sum, the sense of place contributes depth and understanding to what it means to be human.

awe or attachment. Thus, the shift is away from studying humans toward a concern for the qualities or attributes of places that move the individual; this has been called *genius loci*, or the spirit of place. Along this line, most humans have their favorite places (often stemming from their early experiences) as well as a memory bank of their own special landscapes. Most people are searching ultimately for a place to live that “feels right” to them and that they can call home. Some studies of sacred and indigenous places have focused on the concept of the power of place that in some cases has existed through time and many generations.

This focus on the character of special places resonates with many writers, poets, filmmakers, artists, and most other people, and the kinds of places they are attracted to range in scale from microsettings in the natural or cultural landscapes to neighborhoods, lake or river regions, mountain ranges, cities, or even states, nations, and global geopolitical regions. However, as one moves away from direct experiences and memories involving close human contact with places into a larger generalized framework (especially how large numbers of people share their thoughts about places), the result is a more general and reductionist perspective. In going well beyond the direct gaze, they attempt to factor in a larger cultural milieu involving both natural and cultural landscapes as places of meaning (i.e., a knowledge of climatic, ecological, and natural interconnections, and built environments), adding layers of depth to the cognitive world of sensing a place.

A particularly apparent and accessible arena for sense of place lies in the representations of place; they act to capture and convey senses of place via various media. Imaging places in the visual arts makes powerful use of the sense of place. Similarly, many writers feature sense of place in literature, poetry, and metaphors of place. As evocative as these may be, the media production of place in digital news, entertainment, and advertising, through its sheer volume and ubiquity, trumps all (e.g., senses of place of current war zones such as Iraq, inaccessible places such as North Korea’s capital city Pyongyang, places of desire such as those on many television series, and purpose-built resorts such as those in Cancun, Mexico).

Accordingly, the sense of place is fertile ground not only for representing and imagining places but also for creating and contesting it. Thus, the making of place, resistance and place, visualizing and performing place, designing and building places, and geopolitics and place—to name just a few—are all examples of how geographers and others have sought to employ sense of place to better understand certain spheres of human action and interaction. Furthermore, the sense of place can also act as a mediator between a host of analytical binaries, such as transposing conservation with profit; an evocative sense of place not only pleases but is also good business. Even as an ever-increasing placelessness has been identified, new senses of place are also emerging due to human dynamism and creativity. The idea of a global sense of place has been proposed, and everyone who’s ever e-mailed, blogged, networked, or instant messaged through personal computing and the Internet is acquainted with cyberspace—a burgeoning world of new virtual senses of place. Clearly, sense of place can be viewed from many different entry points from which individuals can enter into or continue previous intellectual journeys in their studies of place.

SEQUENT OCCUPANCE

Sequent occupance is a model of landscape change that was widely adopted by American geographers from the 1930s through the 1950s. It views the landscape as a series of superimposed patterns accumulating as culturally distinct ways of life (modes of occupance) that leave their imprint on the land. Each mode is hypothesized to rework the prehuman landscape and earlier cultural layers in distinctive ways, leaving traces visible in the present landscape. The term was introduced by Derwent Whittlesey in 1929. The word *occupance* was in use, denoting the whole complex of human interactions with the land, to which Whittlesey added the idea of a succession of discrete historical layers. In his original paper, he offered as an exemplar a hypothetical small area of New England for which he proposed the following stages: (a) hunting and gathering by Native Americans, (b) farming, (c) the “present” stage (1929) of declining agriculture and rising secondary forest, and (d) a predicted future stage of forestry by nonresident owners.

Whittlesey used ecological and developmental language in his definition. He saw human occupance as a biotic phenomenon and suggested that it obeys rules analogous to a human organism, an analogy that echoes William Morris Davis’s normal cycle of erosion; indeed, in later work, Whittlesey invoked the Davisian idea of rejuvenation. In keeping with the same developmental metaphor, Whittlesey emphasized endogenous changes,

arguing that human occupance contained the “seed of its own transformation.” Nevertheless, he recognized the role of exogenous forces such as the impact of midwestern farming on New England agriculture. Although sequent occupance assumes human adaptation to the environment, it also posits the active reshaping of landscape and can thus be seen as part of the contemporary reaction against environmental determinism.

Until 1928, Whittlesey was at the University of Chicago, associated with a group of midwestern geographers engaged in intense discussion over the nature, content, and technical vocabulary of the emerging discipline. Preston James and Cotton Mather noted the importance of these interactions in the midwestern spring field conferences begun by Carl Sauer and Wellington Jones in 1923. Whittlesey attended many of these conferences, which focused on small-area fieldwork. Other regular attendees included scholars who took up the idea of sequent occupance, including Preston James and Stanley Dodge. Many dissertations and articles employed the concept during the 1930s and 1940s, and James used it in his influential text *An Outline of Geography* (1935). Important exemplars of the method include Stanley Dodge’s work on the Illinois Prairie, Alfred Meyer’s study of the Kankakee Marsh, Lewis Thomas’s work in Missouri, and Edward Ackerman’s study of the influence of Boston on Concord, Massachusetts. Details of these and many other applications can be found in Marvin Mikesell’s account.

A clear aspiration of Whittlesey’s original article was generalization and regional comparisons; he thought it likely that relatively few “sequence patterns” had ever existed. In fact, as studies proliferated, there was little consensus about the number of stages or the criteria by which they were to be defined and very little explicit comparative work. Despite the aim of encompassing the whole complex of human interactions with the environment, stages were most commonly identified with modes of economic exploitation and land use either at a high level of abstraction (e.g., hunting and gathering, agriculture) or at a finer scale of resolution (e.g., dairying, truck farming). Stages were also sometimes identified with indigenous or immigrant ethnic groups. Whittlesey’s original illustrative area in Northern New England had been small (15 square miles),

but subsequent researchers applied the idea across a great range of geographic scales.

One methodological refinement rapidly emerged, argued by Richard Dodge among others. Visibility of relics in the present-day landscape was taken as a necessary condition for the inclusion of past features in descriptive analysis. Thus, sequent occupance came to incorporate a present-centered view of historical time linked to a cross-sectional treatment of the past, conceptually subordinating historical process to present geography. This view of historical geography was akin to that developed by Richard Hartshorne and contrasts strikingly with the emphasis placed on the continuous unfolding of cultural processes by Carl Sauer and the Berkeley School, whose historical accounts tended to avoid cross-sectional analysis.

In its time, sequent occupance offered a useful refinement of geographic vocabulary and a beguilingly simple organizational structure for historical and cultural work. It represents a legacy of an enthusiastic, formative period when American geographers were striving to develop technical terms and procedures distinct from those of other disciplines. The term is occasionally used metaphorically and survived until recently in introductory textbooks. But sequent occupance faded from the research literature of geography during the 1950s. Marvin Mikesell offers some plausible reasons for this decline. Its cross-sectional treatment of the past was not useful for historical geographers and held little appeal for present-oriented systematic specialists, while its emphasis on endogenous change belied the facts of migration and diffusion. Its monolithic treatment of culture and its elision of agency, symbolism, structure, and political economy render it equally uncongenial to most cultural and historical geographers today.

SETTLEMENT GEOGRAPHY

Settlement geography was defined by Fred Kniffen and Henry Glassie as “the interpretable record of the historical events and cultural processes imprinted on the land” and by Kirk Stone as “the description and analysis of the distribution of buildings by which people attach themselves to the land.” Settlement not only has been studied independently but is also included as a component of human/cultural, historical, or population geography. The study of settlement geography historically has chiefly been anthropocentric and was concerned with rural buildings, especially dwellings that offer a snapshot of the cultural background, place, and time of construction.

More recently, the study of settlement has evolved into the interaction of humans with the physical and ecological world. This more holistic study is concerned with sustainability and seeks to better understand the present landscape and plan the future.

Settlement geography has been and continues to be studied far more in European universities. The Germans and the French spearheaded European study a century ago by examining rural farmstead and village patterns. The focus capitalized on the long-lasting European cultural hegemony and impact in world affairs and the rich architectural styles that intertwined over time in the complex patterns that settlement deciphers.

American settlement geography adopted the architectural and spatial pattern concepts of European studies. Settlement geography in America flourished during the time of Carl Sauer's cultural geographic perspective. American settlement studies have generally been either regionally based or mapped on European ethnic groups in America.

Settlement geography has depended on the rural landscape for its subject matter. Rural vernacular farm buildings have been studied for patterns, functions, origins, and relationships to agricultural production. Shapes and functions

often reflect cultural preadaptation (competitive traits possessed by an ethnic group) and simplification (modifying, inventing, or borrowing new traits). The arrangement of land survey systems and roads has also created patterns to be interpreted by settlement. Over time, as America became more urban, the rural landscape evolved into progressively larger urban sites from hamlets to the metropolis. The study of settlement geography remained concentrated on rural settlement patterns, while urban geographers deal with city patterns.

American geographic study reached its apex from the 1920s through the 1970s, during which Isaiah Bowman, Fred Kniffen, Loyal Durand Jr., Glen Trewartha, and Kirk Stone wrote about the topic. Henry Glassie, Terry Jordan, Karl B. Raitz, and William Wyckoff more recently contributed to the field in the United States. Beginning in the 1920s, Isaiah Bowman studied pioneer farming settlement to identify global areas of potential colonization. This type of settlement study is seldom practiced today, having given way to the more historical and European-like study of house types, barns, and agricultural outbuildings. In the 1930s, Sauer's student Fred Kniffen began to study folk housing in Louisiana and then across the Midwest. Louisiana State University carries

forth his methods to interpret vernacular culture research in the Gulf South. Durand, Trewartha, and Stone worked in settlement geography at the University of Wisconsin. Loyal Durand was an economic geographer who studied rural agricultural production of milk from the 1940s through the 1960s and as a by-product studied the shapes of barns throughout the midwestern milk shed. Allen Noble and John Fraser Hart continued regional barn studies into the 1980s.

In the 1940s, Glen Trewartha, a physical geographer, studied settlement types and then applied what he found to the local landscape and patterns. His work explained the rural settlement patterns of compact villages that were often settled by homogeneous groups, as well as hamlets and villages that are differentiated by their size and the number of retail establishments. Kirk Stone was concerned with the definition of settlement and argued for a settlement geography that focused on dwellings within areas of primary production. He also worked in Alaska on a variety of subjects, including the settlement of the Matanuska Valley during the New Deal period, which could be read as a continuation of the Bowman tradition of pioneer settlement.

More recent studies in settlement include the work of Terry Jordan, who specialized in Texas settlement patterns and also folk architecture, village life, and agricultural practices. Henry Glassie, a Kniffen protégé, is a professor of folklore who is known for his material culture and vernacular architectural studies around the world as well as in the United States. Karl Raitz contributed to the study of ethnic groups and American landscapes, the National Road, and Appalachian studies. William Wyckoff published on Western settlement and its ecological imprint on the landscape. In Canada, Cole Harris contributed several works on the historical and settlement geography of the Canadian frontier. Many others have studied the settlement patterns within their home or adopted states. However, the specific study of settlement has declined.

The study of American settlement has historically been within rural America, where the classical authors studied ethnic patterns on the vernacular rural landscape. In time, authors began to study the transition from rural to urban landscapes and, more recently, the less than sustainable, sprawling

urban landscape patterns. Traditional settlement geography may be renewed because of its emphasis on local materials and as a learning tool for sustainable community building. Settlement today can also be studied for the demands it places on land, the environmental impacts, and the altered ecological systems. The current study of settlement geography can learn from past settlement patterns, investigate current patterns, and re-create new patterns that are more ecologically sustainable and community oriented.

SEXUALITY, GEOGRAPHY AND/OF

Geographies of sexuality focus on the idea that there is a spatial component to the connections between sexuality (in all its forms), power, and knowledge. This body of work, following on the heels of the poststructural turn in the social sciences and humanities, is a direct outgrowth of feminist geography. Social and spatial constructions of both gender and sex are invoked through issues of *heteropatriarchy*, which challenges the unequal power relations between those at “the center” (usually heterosexual males) and all other gendered and sexual identities. Lesbians in particular suffer even greater oppression due to the dual constructions of gender and sexuality. As seen through the eyes of lesbian feminist geographers, perceptions of space and place are very important when played out through these manifestations of heterosexual patriarchal power. Sometimes called *heteronormativity*, this assumed or “compulsory heterosexuality” is challenged in geographical research, giving credence and voice to those sexual minorities that are oppressed and marginalized because of their “difference.” Hence, there is a heavy emphasis on identifying how geographical space plays a critical role in defining (and performing) one’s sexual identity. In other words, notions of space and place reveal how particular sexualities materialize themselves on the material landscape.

Much of this work on spatializing sexuality is relatively recent. In the 1970s, a number of things began to take shape that put geographies of sexuality on the map, but not without a struggle. Indeed, the simple act of arranging meetings of gay and lesbian geographers at national and regional academic meetings was often met with hostile denouncements from established scholars within the discipline. During the 1980s, a small number of geographers, mainly associated with the gay and lesbian rights movement, began drawing attention to the way sexual space is produced and acted on.

The earliest significant work in sexuality and space was in urban geography, as scholars sought to map out the most visible lesbian and gay spaces within the North American city. Among the first to publish geographies of the “gay landscape”

was the urban sociologist Manuel Castells, whose treatise *The City and the Grassroots* (1983) was widely cited. His study on the boundaries of the Castro District in San Francisco postulated that gay men (as men) were actively more territorial than lesbians (as women), who relied on informal social networks more than the “brick-and-mortar” commercial spaces (bars, bathhouses, etc.) that were so closely associated with gay men. This was perhaps the first work that drew attention to the spatialized aspects of homosexuality, and it readily drew geographers’ attention. Analyzing the locations of social networks, particularly of lesbian communities, is another theme. It is argued that these networks are fragile and fluid, given the threat of male violence against women in general and lesbians in particular. A third theme explores the intersections of sexuality with everyday life in rural areas. Arguing against an urban-metropolitan bias in sexual geographies, rural spaces are explored, showing that these spaces are numerous, complex, and influential.

Another aspect of geographies of sexuality revolves around “nature-society” relationships, a popular theme in geography that studies the relationship between human beings and their natural or biological environments. In particular, medical geographers, epidemiologists, and others have attempted to map and model the spread of AIDS and HIV globally and nationally. Many of these studies have come under heavy criticism, as they omitted the social and cultural dimensions of sexuality that affect prevention and infection. But recently, a “critical health geography” has emerged, which shows the importance of making sense of the geographies of HIV/AIDS by examining the spaces of the disease and its treatment, as well as the influence of sexual subcultures, institutions, and political activism.

During the 1990s, geographical work on sexualities took on a wider perspective, in part because of the influence of queer theory, which postulates that sexual expression is much more varied and fluctuating and embeds itself within multiple human identities and cultural expressions that play out across time and space. Today, a multiplicity of work exists that varies widely in geographical scale, from sexualized transnational and global spaces to the most intimate of scales, that of the body.

One such narrative deals with cognitive accounts of public spaces at varying scales, ranging from the street and the park to the neighborhood and the community. This research focuses on territorializing and identity formation through urban design, the formation of gay ghettos, public sex as a political act, and issues of domination and control through surveillance. Related to this is the notion that sexuality is deeply embedded, and at the same time external to, capitalist spatial constructions of the individual, the family, the community, and the globe. Sexual minority communities therefore become part of a political-economy narrative, such as the role of sexual minorities (in particular, gay men) in effecting the urban processes of gentrification. Sexuality-driven cultures and spaces, therefore, are folded into economic envelopes of cultural commodification and consumption.

Another aspect of geographies of sexuality revolves around intersections of space and sexual politics, in particular how various sexualities interact with the state at different geographical scales. In line with the postmodern “turn,” this work focuses on aspects of political identity rather than on the processes of urban political economy. This marked a change in focus from urbanized landscapes to how heterosexualized nationalism and citizenship are socially constructed and very much contested. For example, much has been written on the relationship between the state and sexual minorities. A good example is the recent scholarship on the place dynamics of the same-sex marriage issue in the United States. In terms of social, political, and legal rights, the state sometimes excludes gay men and lesbians from full citizenship based on the idea that legal rights and state entitlement programs are reserved for heterosexual family units. Examples include tax benefits for married couples, inheritance rights, custody and adoption rights, and so on. Legal, health, and welfare systems are also based on criticisms of the institutionalization of heterosexuality. Consequently, sexual minorities are discriminated against. Inequalities within social and physical space are created and contested through the politics of intolerance, oppression, and subversion. Related to this notion is a small body of literature on quantitative analyses of voting patterns in gay rights referenda and elections, most

of which argues that both the diffusion of political ideas related to “gay rights” and the so-called culture wars can better be understood by looking at correlations between voting patterns and socio-demographics.

An examination of geographical scale at the level of the body reveals that all bodies are categorized as “sexed” and are socially constructed as male versus female and heterosexual versus homosexual. In this vein, many geographers have made use of Michel Foucault’s account of *biopolitics*. Foucault theorized that beginning in the late 19th century, heterosexual bodies were rigorously defined by the medical and religious communities as “normal,” thereby constructing all other sexualities as “deviant.” As these notions have shifted across time and space, geographers point out that there is no way to escape the cultural and social settings in which our bodies are placed. Human bodies, therefore, become sexualized spaces themselves, in which particular bodies in particular places can disrupt traditionally accepted notions of sexuality. In other words, bodies can be “out of place,” that is, they disrupt fixed categories of identity and space. One particularly interesting example is Michael Brown’s work on how the spatial metaphor of being “in the closet” works to describe the concealment, denial, and ignorance of gay men’s presence in the world and how this is a spatial practice of power and knowledge. This is a geographic extension of previous research on “the closet,” which has come largely from literary criticism and the humanities. Brown situates the closet in different locations and at different spatial scales and shows how this has implications for a wide variety of contemporary social theories and debates.

Criticisms of scholarly work on sexuality from the point of view of mostly white, North American and European gay males have spawned a new body of literature that includes views from perspectives of sexuality as just one of many cultural markers that make up human identities. Multiple identities that combine sexuality with race, economic class, gender, and disability have now become increasingly important in examining sexualized community space. Most recently, research on sexualized geographies has turned toward issues of transnational capitalist global space. For example, various issues are being addressed, such

as how international border crossings, mass migration, and increased mobility have affected sexual minority communities, culture, and politics. Related to these issues of globalization and sexuality is a growing interest in arguments that Western notions of “gay” and “queer” are themselves potentially “neocolonial” and “neo-imperialist.” These mobility/sexuality issues are also being addressed through research on gay and lesbian tourism and travel.

These themes of location, space, place, and movement exemplify how geographers study issues of sexuality. As with any human identity, sexuality is integral to the construction of spatial difference, which requires an understanding of the geographical spaces through which these identities are constructed, performed, and contested.

SHIFTING CULTIVATION

Shifting cultivation, also known as swidden or slash-and-burn in the scientific literature and by countless local names where it is practiced, is one of the oldest and most widespread agricultural

land use systems on Earth. For decades, it has been an important topic of research for geographers who study indigenous and peasant forest dwellers, as well as deforestation and land degradation in the tropics. Shifting cultivation covers an estimated 7.7 million square miles (20 million square kilometers) of arable land and supports 270 million people, or 4% of the global population in 2008. Most shifting cultivators inhabit sparsely settled tropical forests in Africa, South and Southeast Asia, Oceania, and the Americas. In terms of land area, shifting cultivation is most extensive in Brazil, the Congo, and Indonesia and makes an important contribution to food production in these and other nations of the developing world. It is regarded as a major cause of tropical deforestation but has persisted for centuries without serious environmental degradation where low population densities permitted sufficient fallow periods, during which the land is left uncultivated and allowed to return to forest. Although sensitive to population growth and economic change, shifting cultivation systems are now increasingly regarded by researchers and policymakers as repositories of local environmental knowledge that can be critical components of strategies that combine sustainable development with the conservation of agrobiodiversity in tropical rain forest regions.

General Characteristics of Shifting Cultivation

Shifting cultivation involves farmers cutting, clearing, and burning forest vegetation to plant a variety of short-term and long-term crops, typically on small landholdings with little or no use of chemicals, machinery, or other agro-industrial inputs. Shifting cultivators generally do not till the soil, relying instead on fire to clear their fields and on sticks and other hand tools for planting. Shifting cultivation is an extensive system of land use in which farmers grow staple crops in new fields for only a few years before converting them to agro-forestry production or leaving them to forest regrowth. The same plot of land may not be cleared again for staple crops for years or even decades, although the length of time varies according to local environmental, demographic, sociocultural, and economic factors. In this regard, shifting cultivation systems rely on land rotation rather than on crop rotation and fertilizers to maintain soil

fertility. Shifting cultivation systems are remarkably diverse in form and practice, but all mimic to some degree the ecological processes associated with natural forest disturbance and succession.

The production cycle of most shifting cultivation systems starts at the onset of the dry season, the timing of which varies by latitude and region throughout the tropics. Farmers first identify suitable plots for new fields and then clear them with axes, machetes, and other hand tools, as well as chain saws, which are increasingly common in all but the most isolated areas. Forest clearance is one of the most labor-intensive phases of production, and farmers often take the help of relatives and neighbors, who are remunerated for their work through labor reciprocity or with payments of cash or food. The cut vegetation is left to rot where it falls and forms a thick layer of debris that protects the exposed soils during the dry season. In some areas, farmers plant beans (*Phaseolus* spp. and *Vigna* spp.) and other rapidly maturing crops in newly cleared fields amid the decomposing vegetation.

The harvest of dry-season crops, another period of high labor demand, occurs just before the beginning of the wet season. After harvest, farmers burn the dried plant debris in their fields. Under ideal conditions, the vegetation burns well, but often, multiple burns are needed. Burning serves several purposes. It clears the surface of the field and prepares it for wet-season cultivation. It reduces soil acidity and enriches surface soil horizons with carbon, potassium, magnesium, calcium, and other essential plant nutrients in ash. Burning also temporarily eradicates weeds, insect pests, and diseases. As such, insufficient burns due to a short dry season, bad timing, or other factors may lead to a host of problems that hinder the subsequent productivity of a field.

At the beginning of the wet season, farmers plant a variety of staple crops. These vary by geographical region but generally include grains such as maize (*Zea mays*), rice (*Oryza* spp.), sorghum (*Sorghum* spp.), and millet (*Setaria italica*), as well as tubers such as manioc (*Manihot esculenta*), sweet potatoes (*Ipomea batatas*), yams (*Dioscorea* spp.), taro (*Colocasia esculenta*), and dasheen (*Xanthosoma* spp.). Perennial crops such as bananas or plantains (*Musa* spp.), pineapples (*Ananas comosus*), and sugarcane (*Saccharum*

spp.) are also planted at the onset of the wet season, as are a wide variety of fruit and nut trees and other agroforestry crops.

Staple grains may be cultivated once or twice in the same field during a single wet season depending on local climatic and environmental conditions. Weeding becomes important as these crops mature. Shifting cultivators weed by hand, either timing their work to specific growth stages of their crops or weeding continually from germination to harvest. Weeding is tedious work, and farmers often rely on family and neighbors for help. Intercropping, a near-universal practice in shifting cultivation, involves planting different grains and tubers together or alongside beans, squash, and other vegetables. Each crop is then harvested by hand as it reaches maturity. By maximizing the surface area under production, intercropping inhibits weed growth, minimizes crop loss due to pests, and permits a wide variety of crops to be cultivated in the same field, thereby contributing to the subsistence security of shifting cultivator households.

Farmers generally do not cultivate staple grains for more than one wet season, whereas root crops and perennials may remain productive for another year or two. Even after the end of the first wet season, fields become increasingly weedy. *Cecropia* and other secondary species establish a new forest canopy and begin to shade out most perennial crops. At this stage, farmers may decide to leave the field to secondary forest regrowth for a variable number of years before clearing it again for staple crops. In other cases, farmers may convert fields to agroforestry plots and continue to grow bananas and plantains alongside a wide variety of tree crops. Agroforestry, which requires less labor than staple crops, is a long-term investment that contributes to nutrition while providing a perpetual source of natural medicines, building materials, and other household products, as well as potential cash income. As tree crops die out after decades of production, old agroforestry plots are again cleared for staple crop cultivation.

Ecological and Economic Dimensions of Shifting Cultivation

Shifting cultivation is one of the oldest systems of agricultural land use on Earth, and its origins

likely date to the beginnings of farming around 10,000 years ago. Because it requires no plowing and little more than fire, wood-cutting tools, seeds, and minimal amounts of labor for food production, shifting cultivation was likely the original system of forest farming across the tropics and in the midlatitudes of Eurasia and the Americas. Population growth and landscape change led to the gradual adoption of more intensive agricultural systems in the midlatitudes, but shifting cultivation endured in the forested regions of the tropics. Recent archaeological evidence from Central and South America, West Africa, and Southeast Asia suggest that it may have played an important role in prehistoric food production throughout the tropical world, coexisting alongside more intensive systems of agriculture and even replacing them during periods of socio-political upheaval and demographic collapse.

Contemporary shifting cultivation is often associated with agricultural colonization in the humid tropics and as such is seen as a major factor of tropical deforestation. Since the mid 20th century, growing numbers of poor, landless colonists, attracted by government land distribution schemes, infrastructure development, and hopes of economic advancement, have encroached on the last remaining tropical forest regions on Earth. Lacking capital and technology, these peasant colonists typically practice shifting cultivation for subsistence. As the populations along tropical forest frontiers grow, colonists must often shorten their fallow periods in response to increased settlement densities and land scarcity, often compromising the ecological integrity of their land use systems and inciting deforestation and soil degradation. If frontier populations continue to rise, colonists generally move elsewhere in search of new land, thereby fueling renewed frontier expansion, or abandon shifting cultivation to become laborers for large-scale enterprises engaged in logging, ranching, and plantation agriculture.

Agricultural colonization in the tropics also affects the shifting cultivation systems of indigenous forest dwellers, some of which are remarkably complex and based on sophisticated knowledge of rain forest environments. In recent decades, shifting cultivation by indigenous forest dwellers has been disrupted by agricultural colonization and greater integration with market

economies, with the most frequent consequences being the shortening of fallow periods and the abandonment of agroforestry production. Some forest dwellers are able to maintain long-term ties with outside markets without sacrificing their subsistence needs or the integrity of their land use practices. In most cases, this is the result of specialization in profitable agroforestry crops such as Brazil nuts (*Bertholletia excelsa*), cocoa (*Theobroma cacao*), vanilla (*Vanilla planifolia*), or various latex bearing trees (e.g., *Castilla elastica*), which are valuable agricultural commodities that provide a steady source of cash income. In the absence of such cash crops, however, shifting cultivation becomes marginalized and is often replaced by more lucrative land use activities as forest dwellers become more oriented toward cash economies.

Shifting cultivation has the potential to be either ecologically sustainable or destructive depending on how it is practiced, but most frequently, it has been portrayed in a negative light. Accounts by early travelers in the humid tropics often described it as a primitive and inefficient mode of agriculture. Likewise, colonial administrators generally regarded it a threat to timber resources and sometimes attempted to suppress its practice. Even today, shifting cultivation is most recognized for its role in deforestation despite growing evidence of its sustainability where farmers maintain sufficient fallow periods and ensure regeneration of forest soils and vegetation. In a properly functioning system, most land is devoted to agroforestry crops or secondary forest regrowth, with only a small portion of land used for staple crops. In this sense, the impact of shifting cultivation on rain forest environments is considerably more benign than the impact of logging, cattle ranching, or commercial agriculture.

Growing awareness of the potential sustainability of shifting cultivation has begun to foster change within the international development community and among academic researchers. Many now regard this simple land use practice as a model of sustainability and an example of how human populations can simultaneously use and protect tropical rain forest ecosystems. Shifting cultivation is also valued for its role as a repository of local environmental knowledge and in situ

agricultural biodiversity. Although it remains vulnerable to disruption from a variety of factors, shifting cultivation is now increasingly regarded as an integral part of initiatives that seek to combine biodiversity conservation with efforts to strengthen the cultural identities and improve the livelihood opportunities of indigenous rain forest dwellers across the humid tropics.

SHORTEST-PATH PROBLEM

The shortest-path problem is one of the most basic and widely applied forms of network analysis used in computational geometry and geographic information systems (GIS). Networks, or graphs, are used to model linear features such as roads and streets using a series of connected nodes (vertices or points) and links (edges or lines). Nodes typically represent the locations of origins, destinations, and intersections, while links are constructed as line segments that connect the nodes. Each link in the network is assigned a weight or cost that is associated with moving from the starting to the ending node. Weights can be assigned based on segment length, weighted distance, or other cost, such as expected travel time. The shortest-path problem then is used to determine the optimal pathway along the network that connects origin and destination nodes such that the sum of the constituent links in the pathway is minimized. If a weighted cost is used in the problem, the shortest path is often termed a *least-cost* path.

Four basic types of shortest paths are recognized, and they are classified based on the number of origin and destination nodes specified in the problem. The simplest is the one-to-one shortest path, which defines a single pathway connecting an origin to a destination node. The one-to-many shortest-path problem determines the set of shortest paths for a single origin to numerous destinations, while the many-to-one problem is used for multiple origins to a single destination. Finally, the many-to-many problem is used to compute shortest paths between all pairs of origin and destination nodes in a data set. These types of shortest-path problems are typically solved using computer algorithms developed for GIS or other software. These algorithms are typically developed for a specific type of shortest-path problem, such as Dijkstra's algorithm, which solves the one-to-many problem, and the Floyd-Warshall algorithm, which solves the many-to-many problem.

Shortest-path problems are widely applied for transportation and routing problems in GIS and related fields. The most common application is for determining driving directions from a starting

to an ending location on a road network, where the goal is to determine the shortest or quickest route between locations. Web-based mapping applications that provide driving directions use shortest-path algorithms to compute their solutions. Shortest-path problems are also used as an input to many other spatial analyses in geography, particularly for location-allocation models, analyses of urban spatial structure, and vehicle routing problems. For example, in a study of commuting patterns in an urban area, the shortest paths between people's residences and work places might be used to estimate the lengths of their daily commutes.

SINGLE LARGE OR SEVERAL SMALL (SLOSS) DEBATE

The single large or several small (SLOSS) debate, which occurred in ecology, conservation biology, and biogeography from 1975 through the 1980s, dealt with the relevance of the dynamic equilibrium theory of island biogeography to the design of refuges or reserves for conservation. This entry describes the equilibrium theory of island biogeography, its application in “habitat islands,” and its use by conservationists seeking to design reserves or refuges for species preservation. It then describes a controversy ignited by the theory and evaluates its relevance today.

Equilibrium Theory of Island Biogeography

In the 1960s, Robert MacArthur of Princeton University and Edward O. Wilson of Harvard University proposed a new explanation for the distribution of animal and plant species on islands: the equilibrium theory of island biogeography. They envisioned the biota of an island to be a dynamic rather than static entity, with species new to the island arriving occasionally (“immigration”), while ever so often the population of some species on the island would dwindle to the point that the species disappeared (“extinction”). They asserted further that the immigration rate would be a declining function of the number of species present on the island (because the more species that are already on an island, the fewer there would remain in the vicinity that could possibly immigrate), while the extinction rate would be an increasing function of the number of species already present (because the more the species that are present on the island, the smaller the population sizes of each would be, on average, and therefore the more at risk of extinction each would be). A rising extinction curve would cross a falling immigration curve at a particular point, which would constitute a dynamic equilibrium number of species (Figure 1). A further consequence predicted by this model was that, other things being equal, a large island would have a larger equilibrium number of species than a small island because the extinction curve would be lower. This would follow from the fact that if two islands had the same number of species, the larger one would have larger population sizes, on average, of each species, so extinctions would happen less frequently. Another prediction of the model is that, other things being equal, the more isolated an island is, the fewer the species that would exist at equilibrium (because immigration rates would be lower).

The equilibrium theory struck a highly responsive chord among biogeographers and ecologists, who quickly began seeking data on island biological communities, or parts of communities (such as all the bird species, or all the mammals, or all the plants), to attempt to match them to the predictions of the theory. Especially common were studies showing that, within single archipelagoes, larger islands tended to have

Note: P is the number of species in the entire regional species pool, and $\bar{S}$ is the equilibrium number of species attained when the extinction rate E equals the immigration rate I .

more species than smaller ones, just as the theory predicted.

Application of the Theory to Habitat Islands

In their original exposition, MacArthur and Wilson suggested in passing that their theory should apply not only to oceanic islands but also to “habitat islands”—pieces of one habitat embedded in a matrix of another. Examples include freshwater lakes, woodlots or small forest patches in an agricultural landscape, and small abandoned fields amid large tracts of forest. The 1960s and 1970s saw the growth of interest in two other areas that intersected strongly with this suggestion by MacArthur and Wilson. First, beginning in the 1940s but increasingly in the 1960s and 1970s, biologists and geographers published papers showing that certain habitats were being progressively destroyed and fragmented, so that what had formerly been continuous “seas” of some habitat had become a series of increasingly small and isolated fragments in a sea

of some sort of human habitat, such as agricultural fields and housing subdivisions. Well-known and widely publicized examples of this sort of change depicted the fragmentation of formerly continuous forest in an area of Wisconsin and of heathland in Southern England, so that forest patches in the first case and remnants of heath in the second became isolated habitat islands. The authors of these publications frequently expressed concern about the consequences of this fragmentation for the species that had evolved in these habitats and were adapted to life in a continuous rather than fragmented range. Would they be able to persist in small, isolated habitat patches?

Habitat Islands and Conservation

The 1960s and 1970s also saw rapidly increasing concern about environmental and conservation matters in general. The first Earth Day in the United States was in 1970, the U.S. Endangered Species Act was passed in 1973, and the U.S. National Forest Management Act was passed in 1976. Newspapers were rife with articles on the loss of species and habitats, and many popular books on aspects of these problems appeared at this time—for example, Paul Ehrlich’s book *The Population Bomb* in 1968. It was inevitable that the theory of island biogeography would quickly be applied to habitat fragments in a conservation context, and this application happened with a vengeance with three papers that appeared almost simultaneously in 1975, by John Terborgh, by Jared Diamond, and by Edward O. Wilson and E. O. Willis. All suggested the relevance of the dynamic equilibrium theory of island biogeography to the design of refuges or reserves for conservation. The latter authors diagrammed a series of rules for refuge design that they associated with the equilibrium theory (Figure 2), and this rule set diagram was subsequently adopted in the World Conservation Strategy of the International Union for Conservation of Nature in 1980. The first rule is that a single large reserve is superior to a set of small ones of equal total area. This rule quickly became known by its acronym SLOSS.

Conservation planners and policymakers, desperate for effective ways to conserve biodiversity in an increasingly difficult sociopolitical context, and with species disappearing regionally and even

Figure 2 The rules of refuge design. In each case, the configuration on the left is deemed superior to that on the right. Rule (a) is the SLOSS rule.

globally at an increasing pace, eagerly turned to these new straightforward, simple rules, which quickly appeared in introductory textbooks, journal articles, and even the guidelines of the World Bank for the environmental aspects of development loans. In practice, many factors other than ecological ones go into decisions about which lands to attempt to preserve in specific cases. Economic, political, and sociological considerations all come into play. However, the rules, and especially the SLOSS rule, at least provided an apparently simple target that planners might aim for. The rule also suggested a shift in what was a dominant conservation strategy at the time: buying up small tracts of land that included known populations (in some cases, the last known population) of an imperiled species. If very small populations, and even collections of several very small populations, were doomed to quick extinction, then it would surely be more efficient to sacrifice

some of the total area in order to sequester larger continuous tracts of land.

The SLOSS Controversy

The SLOSS rule soon ignited substantial controversy that raged for over a decade. It was shown that most of the rules for refuge design, including the SLOSS rule, were not really consequences of the equilibrium theory but rather rules of thumb inspired by the metaphor of refuges as islands in a sea of development. They might still be good rules, but this would be an empirical matter that could be determined only by studying specific situations and determining in particular circumstances whether there was any trend for a single large site to contain more species than several small sites of equal total area.

Also, certain considerations cast some doubt on the dictum that a single refuge, even a rather large one, is always a better design than several small ones. Briefly, in several instances of real oceanic archipelagoes, introduced predators have eliminated populations of a particular species on every island they reached, and the species persists only on one or a few islands, usually small and isolated, that remain predator-free. For example, in the Seychelles Islands in the Indian Ocean, the Seychelles magpie robin persisted only on Frigate Island, which is small and isolated, when cats on the island were removed only after they had eliminated the species everywhere else in the archipelago. Subsequently, the species has been reintroduced in three other islands where cats have been eliminated or controlled. If the Seychelles had been only one large island, this species would be extinct. This example suggests that the optimal refuge design might be different if the area under consideration is the sole repository of a species of concern, rather than simply a site or a set of sites that contains good representatives of more widely distributed species, and depending on what specific factors threaten the existence of that particular species. On the other hand, it is evident that if all the sites in a network of small sites are so small that none can sustain a viable population of some species of concern, then such a network, even if it contained many sites, would be inferior to a single site of equal total area.

Many biologists, seeking empirical guidance on the utility of the SLOSS rule, compared the actual numbers of species in sets of small oceanic or habitat islands with the numbers in single large islands of approximately equal total area. Although there was much variation in the results of such comparisons, the surprising pattern was that, in most cases, the set of small islands had as many species as the single large island or even more. This result does not lead conclusively to a rejection of the SLOSS rule, however, for two main reasons. First, these studies looked at sets of sites that had existed in their current form for long periods of time—at least centuries and often many millennia—and the species on them might thus have been adapted to the fragmented geographic configuration. In contrast, conservationists are concerned particularly with saving sets of sites in landscapes that are rapidly fragmenting in the short term, and it could be that some species in the original continuous habitat cannot adapt evolutionarily, at least in the time frame of concern, to existence in a set of small fragments.

Second, this entire exercise, and in fact the theory of island biogeography that inspired SLOSS, is aimed at simply maintaining the largest number of species in the reserve or set of reserves. However, conservationists are not nearly as concerned about the number of species in a specific site as in saving species from regional or global extinction. If a set of small sites had many species in total, but all of them were quite common and widespread, this would be less important from a conservation standpoint than if a single large site had fewer species in total but among those species were one or more not found anywhere else. In short, the requirements of restricted and rare species generally trump the desire to maximize the number of species in every reserve. And there is abundant evidence that many species do require large sites for a variety of reasons and that among these species are many that are quite rare. For example, large carnivores need large sites simply for purposes of sustenance—they require more prey for subsistence than can be found in small sites. Many plant species are restricted to the interior of forests; some are never found less than hundreds of meters from a forest edge. A set of small sites would not suffice to conserve these, no matter how many small sites there are.

A final consideration is that conservationists, though not neglecting isolated small populations of imperiled species, are increasingly trying to preserve entire landscapes so as to preserve the ecological processes that maintain the habitats required for whole suites of species. Sometimes this is difficult or impossible to achieve unless large, quite continuous areas are preserved. For instance, many forest types, including the longleaf pine forests that used to dominate the southeastern United States, are fire disclimaxes, maintained only by frequent low-intensity fires. In the absence of such fires, other plant species replace the species typical of these fire disclimaxes, and the entire community, both plants and the animals that live in and on the plants, changes greatly. In the Southeast, such fires are initiated fairly frequently by lightning; such fires used to sweep unimpeded over many kilometers, so the whole landscape routinely burned. Today, old-growth longleaf pine forests are restricted to small fragments isolated in a sea of agriculture, highways, and other human constructs. The likelihood of a lightning strike within any one fragment is low, and even if a fire is initiated in a fragment, it cannot spread to other longleaf patches. An expensive technology of prescribed fire must now be used to maintain longleaf forest communities.

Today, SLOSS and other rules—those originally inspired by island biogeographic theory and others deriving from more recent sources—are viewed as rough guidelines at best, and the idiosyncratic factors, both biological and nonbiological, that obtain in any real conservation situation are taken into account. These include the habitat requirements, distributions, and evolutionary distinctness of the species particularly targeted for conservation; the economics of different refuge options; the security of possible refuge configurations with respect to introduced species and anthropogenic damage; and the social and economic concerns of the various stakeholders. In this light, SLOSS can be seen as an early attempt to formalize some of the biological considerations of importance to long-term conservation and as a continuing heuristic device to be used, along with other inputs, in an attempt to optimize conservation planning.

variety of different subfields, including cultural and political ecology, geographic information systems (GIS) and society, and economic geography. Specific research foci deal with the customary knowledge systems of indigenous peoples, transformation and representation of local knowledge as a means of democratizing GIS, and spatiality of knowledge in postindustrial societies and global capitalism. Geographers and other researchers use various terms to refer to this concept, with *local*, *indigenous*, *informal*, *expert*, and *traditional knowledge* being most common. The variations in terminology may reflect subtle nuances in meaning, but all refer to alternative knowledge systems that arise, often experientially, as a result of differences along the lines of ethnicity, gender, class, culture, occupation, and other factors.

Ethnoecology, or ethnoscience, studies the customary knowledge of indigenous peoples and traditional rural societies and is the oldest, most well-established area of research on situated knowledge. Since its emergence from anthropology in the 1950s, ethnoecology has grown into a dynamic, interdisciplinary field in which geographers, particularly those specializing in cultural and political ecology, have made important contributions. Much of the early ethnoecological research by geographers took place in isolated settings such as tropical forests, mountain regions, and deserts and produced detailed accounts of subsistence and resource management practices from which researchers examined the ecological rationality and knowledge of local peoples. More recently, geographers have sought to contextualize their work within broader scientific debates on topics such as agroecology, sustainability, biodiversity conservation, and protected area management. Some have explored native perceptions of space, place, and the environment, demonstrating that the knowledge of the inhabitants of isolated regions around the world is often more accurate and detailed than Western science. Others have studied situated knowledge from the standpoint of power by examining the interactions between indigenous peoples and mainstream society, the state, and international organizations. A number of geographers have also used participatory methods in a variety of applied research contexts to integrate

SITUATED KNOWLEDGE

A growing consensus in the social sciences and humanities regards knowledge as inescapably situated within the broader spatial, temporal, socio-cultural, and political economic contexts. This view has contributed to a rejection of logical positivist science as the only legitimate source of knowledge and has fostered acceptance of the idea that multiple epistemologies, or ways of knowing the world, are valid. An emergent body of research on situated knowledge explores these alternative epistemologies and their linkages with mainstream knowledge and global society. Geographers have focused on this concept in a

the customary knowledge of local peoples with conservation, protected area management, land reform initiatives, and natural hazards mitigation.

An emergent body of literature that focuses on GIS and society, or the social implications of GIS, has also contributed to scholarly research in geography on situated knowledge. Some argue that GIS itself, and especially the human organizational frameworks in which it is embedded, is a form of situated knowledge. Participatory and public participation GIS explores how the situated knowledge of marginalized peoples can be integrated with geospatial technologies so that its original contexts and meanings are preserved and accurately represented. Much of this work examines the efforts of nonprofit organizations to use GIS as an advocacy tool for low-income residents of cities in the United States and elsewhere in the industrialized world. Rich in case studies, participatory and public participation GIS research is contributing to new methods of transforming the experiential knowledge of the urban poor to bring about progressive change in their lives. Some researchers have pursued these goals by revising the organizational model of GIS to more effectively integrate situated knowledge as data. Others have sought to develop enhanced metadata systems that provide greater flexibility of data storage and that allow multiple file formats, particularly multimedia, to be incorporated as ancillary information. Still others have used computer programming to engineer solutions that enhance the usability of GIS or to custom-design GIS applications that meet the specific needs of disadvantaged populations.

A third area of research on situated knowledge is in the subfield of economic geography, where recent studies have examined the linkages between industrial location and expert knowledge in global society. The rise of the digital age has brought about the unprecedented decentralization of information and production in the global capitalist system. This transformation of global society, however, has coincided with a contradictory trend in which critical sectors of the information economy have become spatially clustered. Most high-technology centers are products of long-term investments on the part of industry, governments, and universities. Decades

of incentives have not only created conditions for information economies to take root but also led to the spatial concentration of capital, resources, and labor around high-tech hearths. This is particularly true of information professionals, who generally live near centers of high technology and whose expert knowledge forms an important component of human capital within the global economy. Researchers have found that transnational corporations must maintain a local presence in high-tech areas to successfully attract qualified knowledge professionals while cultivating their international scope to remain globally competitive.

SMART GROWTH

Smart growth, a term that appeared in the urban geography and planning literature in the mid 1990s, signifies the need to adopt policies as countermeasures for urban sprawl. The latter is defined as the outward expansion of the limits of an urban area through the development of low-density suburbs, where it is uneconomical to sustain public transportation systems. The results are excessive use of the private automobile, an increasing number of work hours lost in traffic congestion, and a rising volume of automobile emissions. The latter is associated with greenhouse gases that are responsible for global warming and the

deterioration of urban air quality with the formation of ozone and smog, which have significant detrimental effects on human health and the city infrastructure.

Other detrimental effects that smart growth would remedy are the loss of agricultural land near urban areas and the deterioration of inner cities. The latter comes about by the reduction in housing demand at the city core, the associated drop in housing prices, and the reluctance of homeowners to expend capital for the maintenance of their property. Furthermore, the proponents of smart growth point to low-density suburban development as responsible for the reduction in social interaction and the weakening of the bonds that characterize a healthy society.

Aerial view of Premier Gardens Zero Energy Home Community in Sacramento, California. Designed to save homebuyers up to 60% on utility costs, this community combines innovative construction and energy-efficient appliances with renewable energy to create homes that not only are energy efficient but also produce their own electricity.

Source: Sacramento Municipal Utility District.

While there is no widespread acceptance among planners, decision makers, and researchers as to the path that would lead to smart growth, two types of policies have been proposed and implemented. The first can be labeled *land use* policies and relates to restrictions in land development, the most common of which is the imposition of a greenbelt boundary around an urbanized area, beyond which development is not allowed. Critics argue that such a policy may encourage *leapfrog* development outside the greenbelt, thereby increasing the detrimental effects of sprawl.

The second type of policies considers sprawl as an *economic* process and proposes the design of instruments that will stabilize and even reverse the process. Sprawl is viewed as the result of population growth, rising household incomes, and the falling cost of commuting. These phenomena set the stage for processes that are not fully accounted for in the market (externalities), including the full cost of suburban infrastructure development and maintenance and the social cost of congestion. Remedies proposed are development and congestion taxes levied on consumers. The most common of such instruments is the imposition of a toll on those entering with a vehicle into a city center that is usually well served by public transport. The most well-known example of such a toll is in London.

SMITH, NEIL (1954–)

Neil Smith is among the most influential and famous of living geographers. He is currently Distinguished Professor of Anthropology and Geography at the City University of New York (CUNY) and was the founding director of the Center for Place, Culture and Politics in the Graduate Center at CUNY.

Smith was born in Scotland in 1954 and studied for a BSc degree in geography at the University of St. Andrews. In 1977, he left Scotland for Baltimore, where he began his PhD research on gentrification under the supervision of David Harvey at Johns Hopkins University, graduating in 1982. Though younger than Harvey, Smith underwent a similar academic and political transformation to that of his supervisor. This trajectory entailed a rejection of the kind of geography taught to him as an undergraduate—the so-called new geography or spatial science that Harvey's late-1960s writings embodied—and an embrace of the Marxist approach that Harvey pioneered in his 1973 book, *Social Justice and the City*. It is above all as a Marxist geographer that Smith has made his name.

Like Harvey, Smith has built carefully and creatively on the late political-economic writings of Karl Marx. He has made germinal contributions in four areas—three of them beginning with his book *Uneven Development*, published 2 yrs. (years) after he graduated from Hopkins. First, he is responsible for the “rent-gap” thesis on studies of gentrification and urban redevelopment. In opposition to theories that posit urban professionals as welcome “pioneers” returning to blighted inner-city neighborhoods, Smith's thesis focused on the political economy of gentrification, suggesting that only when the gap between the actual and potential ground rent is sufficiently high do waves of gentrification occur. This thesis pointed to the class dynamics of land use and the power of rentiers and investors to govern the uses of urban space. Highly political questions thereby arise about who has a “right to the city.”

Second, Smith popularized the counterintuitive idea of the “production of nature.” His claim in *Uneven Development* is that in a capitalist world, nature is no longer natural but, instead, is actively

produced at a discursive and material level in the service of capital accumulation. This “denaturalizing” move usefully focused some geographers’ analytical attention on the processes that remake nature (e.g., in commercial agriculture), and it also posed a challenge to those whose politics is founded on ideas of a nonsocial nature with supposedly intrinsic capacities and values.

Third, also in *Uneven Development*, Smith presented a powerful Marxian account of uneven geographical development (UGD). Unlike some other theories of UGD, Smith did not look to the “natural differences” in geography to explain the phenomenon. Instead, he argued that capitalism both produces and needs UGD: It is part of the system’s operating hardware, as it were. This means that UGD is a socially constructed phenomenon and thus, in theory, entirely preventable. Finally, *Uneven Development* also advanced the challenging idea that geographical scale is socially produced and a tool of power—thus being more than simply a mental category that we use to divide the world up. Smith argued that capitalism (including the capitalist state) actively organizes commodity production, distribution, exchange, and consumption at certain scales at certain historical moments. These constructed geographical scales become containers, constrainers, and enablers of different sorts of activities undertaken by different groups—producers, rentiers, politicians, financiers, trade unionists, and so on. Geographical scale, for Smith, thus enters into the very fabric of capitalist life and struggles to alter and transcend it.

Smith has advanced his work in all four areas both empirically and theoretically over a 30-yr. period. He is a prolific writer and speaker. He is also a founder member of the International Critical Geography Group (ICCG), which seeks to bring together left-wing scholars and activists of various stripes who are committed to radical reform of the current world order and, better still, revolutionary change. He has also, in his recent *Endgame of Globalisation*, sought a more public profile for his otherwise quite academic writing.

SOCIAL AND ECONOMIC IMPACTS OF CLIMATE CHANGE

Climate change is mainly concerned with the impacts on people, beyond narrow interests in natural science. For instance, the tundra may be thawing in the polar regions, which can be of scientific interest in its own right. But the more important question is what difference it makes for economies, societies, governance, and human well-being. This question is growing in salience as the knowledge base about climate change improves. About *whether* climate change is happening, there is now a very broad consensus that global warming is a reality. About *why* it is happening, the Fourth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) reports persuasive evidence that human activities are an important cause. The remaining issue is “*So what?*” Humanity has been adaptable throughout its history to innumerable challenges. Is climate change something that will present important challenges, or is it just one of many driving forces of social and economic change over the next century and beyond?

Current Knowledge About Social and Economic Impacts

Some impacts of climate change are already being observed, mainly in the polar areas, where traditional societies are finding it difficult to sustain their ways of life and modern societies are facing the impacts of a thawing tundra on physical infrastructures. But in most cases, the recent major climate events in the United States—such as Hurricane Katrina in 2005 and Hurricane Ike in 2008, along with a summer heat wave in 2006 and regional water shortages in the winter of 2007–2008—cannot be attributed to climate change because climate has historically been so variable. These events can be considered examples of the impacts that could become more frequent with climate change, which is very instructive; but they cannot be interpreted with a high degree of confidence as impacts of climate change itself.

The more serious issues lie ahead. What might climate change mean for economies and societies in the long run? Climate change is expected to mean increases in average temperatures, more severe toward the poles; changes in both the total amount and the intensity of regional precipitation; changes in the intensities and locations of severe weather events; and sea-level rise. Clearly, such changes could be important in many locations, but projecting the impacts on human systems in the long term is complicated since other things will also be changing over that period, such as demographic patterns, global economic relationships, available technologies, and institutional structures and practices. The socioeconomic effects of climate change will depend on how climate change interacts with these other kinds of change. Consider, for example, how much climate change might increase by 2080 the vulnerabilities of people living in coastal areas subject to sea-level rise and seasonal storms. By that time, populations in vulnerable areas will have had three generations of experience with storms and coping strategies, from risks of storm disruptions and damages to increased costs and reduced coverage of losses from private insurance. Voluntary retreats from vulnerable coastal areas may have reduced potential damages considerably.

For this reason, assessments of socioeconomic impacts of climate change generally focus not on

projections of long-term impacts, based on quantitative scenarios of direct climate change over periods of a century or more, but on climate change risks and vulnerabilities. In other words, rather than assuming a particular level of climate change in the far future, without equivalent assumptions about changes in socioeconomic contexts, analysts look at the sensitivities of human systems to climate variables: For example, based on experience with climate variability and other known factors, what difference would a change in average temperature or precipitation make, for instance, for energy requirements, for snowfall on ski resorts, or for disease vectors affecting human health? What is the range of effects of different magnitudes and rates of such a change in climate? In many cases, quantitative analysis is used not to produce hard numerical answers but to inform robust qualitative judgments about the large versus small, the urgent versus cautionary, the known versus unknown, and other guidelines for both decision making and further research.

Assumptions about the possible range of magnitudes and rates of climate change are usually drawn from quantitative scenarios such as the IPCC's Special Report on Emission Scenarios (SRES) family of depictions of possible futures, widely used in the late 1990s and through most of the first decade of the 21st century. Such scenarios commonly use average global warming (in degrees centigrade [$^{\circ}\text{C}$]) as a proxy for the host of physical changes, not necessarily meaning to imply that temperature changes are the most important of those changes. Most of the SRES project average warming in the range of about 2.5 to 3 $^{\circ}\text{C}$ by 2100.

Present knowledge of the social and economic impacts of climate change is limited because support for impact research has been scarce compared with support for climate change modeling. IPCC assessments, however, have indicated that at levels of warming below about 3 $^{\circ}\text{C}$, impacts are likely to be a mixture of positives and negatives, while above that level, impacts are likely to be very largely negative (Figure 1).

At this still early stage in the evolution of understanding of climate change impacts and responses, the greatest concerns about socioeconomic impacts are for vulnerable low-income areas with limited adaptive capacities and resources (including the

Figure 1 Reasons for concerns about projected levels of climate change
Source: International Panel of Climate Change (IPCC), 2001.

polar regions, low-lying island or coastal nations, and much of Africa), increased risks of disruptive extreme weather events (such as the effects of a combination of sea-level rise and more intense tropical storms on densely populated Asian megadeltas), and potential for abrupt (rather than gradual) changes (such as a significant change in the behavior of the Gulf Stream in the Atlantic Ocean).

More specifically, but still in very general terms, dry areas are expected to become drier and wet areas are expected to become wetter, while water storage in snow cover and glaciers will decline. Many ecosystems will face stress thresholds, especially if the average temperature increase exceeds 3 °C. Global food production could increase at lower levels of warming, but it is expected to decrease at levels above 3 °C. Potentially serious health effects are projected, especially for vulnerable populations.

These kinds of effects vary in their impacts by sector as well as by region. Sectors that inherently have greater sensitivity to climate—such as agriculture, commercial forestry, and recreation/tourism—are relatively more vulnerable, as are sectors with concentrations of activities in vulnerable regions such as coastal areas, river valleys, and areas of water scarcity—such as energy facilities in the U.S. Gulf Coast region.

But in nearly every case, the socioeconomic impacts are not well estimated from averages. Particular regions, sectors, and population groups are more often affected by where they stand with respect to variance around the mean change and by associated extremes (*very* high or low, even for relatively short periods). Analyzing such impacts with any accuracy, along with the potential benefits of reducing impacts and the costs of failing to reduce them, requires attention at a relatively detailed scale: geographically, sectorally, socially, and temporally. In many cases, for instance, an assessment of impacts at a large geographic scale may conclude that the risks are relatively small at that scale, while risks to an exposed local area could be quite large at that scale. Both can be true. An example is estimating the economic costs to the United States as a whole from a major coastal hurricane (very small as a proportion of the national economy) compared with the economic costs to a locality directly in

the path of the hurricane (dramatically large for a period of many months).

Responses to Concerns About Impacts

Where prospects of climate change impacts raise concerns, the risk management responses are mitigation and adaptation. Mitigation includes fuel switching, away from fossil fuels to renewable energy sources or nuclear energy; energy efficiency improvement; increasing uptakes by biomass, soils, or the ocean; and technology breakthroughs such as affordable carbon capture and sequestration during energy combustion/conversion processes. Adaptation includes increasing the resilience of vulnerable systems, emphasizing cost-effective steps that also reduce current stresses; increasing the range of alternatives and resources available to reduce the risks of impacts; and improving emergency response capabilities. Most analyses indicate that reducing climate change impacts enough to avoid painful costs to many social and economic systems in some parts of the world will require doing the best we can with both mitigation and adaptation. Success with mitigation can keep climate change moderate, so that adaptation can cope with a majority of the impacts. Adaptation can enable less demanding and more realistically plausible targets for mitigation to avoid dangerous impacts.

The greatest concern is that, because of the slow progress with global mitigation efforts to date, especially due to the growing carbon emissions from large developing economies in Asia, climate change by the latter part of the 21st century will be more severe than previous assessments had considered likely, posing the possibility of dramatic social and economic impacts in many cases. Observations during the first decade of the 21st century indicate that the physical impacts of climate change, such as glacier retreat or ice sheet thinning, are emerging more rapidly than projected even a few years earlier, and they indicate that global greenhouse gas emissions are growing by more than 3% per year, compared with about 1% during the 1990s. Given these observed trends, impact analyses are beginning to consider scenarios that could result in average global warming of 5 to 6 °C by 2100, rather than the earlier prediction of 2.5 to 3 °C. Early analyses

indicate the likelihood of very severe impacts by the latter part of the century if the world continues on its course toward higher levels of impacts. As an example, a study of possible climate change impacts on nine northeastern U.S. states, using the highest of the SRES as one of two cases, projected that with this relatively severe climate change, the 100-yr. (year) flood in the Atlantic City, New Jersey, area would by the end of the century be expected to occur every 2 yrs.

Contributions of Geographic Perspectives

Academic disciplines are means to social ends, not ends in themselves; the socioeconomic impacts of climate change are transdisciplinary. But geographers have been leaders in developing the science and art of climate change impact assessment, at least in part because many of geography's perspectives are useful. First, climate change is a classic nature-society issue, and geography is one of the very few disciplines whose traditions and research literatures span that gap. Second, geography is the leader, in both science and practice, in focusing attention on the value of place-based studies (and, by extension, other small-scale analyses) for integrated evaluations of climate change impacts. Third, spatial systems are important in evaluating the impact risks of and vulnerabilities to climate change, not only as a place-specific issue but also in terms of linkages with other places. For instance, among climate change impacts are threats to bridges, highways, communication networks, and other facilities that link different places and activities together. Moreover, the impacts of climate change on a particular place are not limited to what happens at that geographic location; that place can also be affected by climate change in other places that are its sources of inputs, its markets, and its competitors in the global economic marketplace. Finally, climate change impact assessment is closely linked with integrative regional knowledge, because social and economic impacts depend so substantially on other aspects of a region's environment, economy, and society. In these ways and others, geography is a key contributor to assessments of the social and economic impacts of climate change.

SOCIAL CONSTRUCTION OF NATURE

There is a long tradition within geography in which study of the human relationship with nature is central. What nature is considered to be would thus seem to be of crucial importance to this tradition. Yet until very recently, the nature of nature has not been considered much. Nature is usually assumed, absorbed as taught, unquestioned, and generally commonsensed to be something independent of the human world. According to this view, the human world affects nature, but the two realms remain distinct.

The notion of the social construction of nature resulted from the attempt made by many scientists to reconsider this common understanding of nature in relation to humans. To do this requires questioning all received wisdom with regard to both sides of the nature-society relationship, and even the idea that this is a relationship between two distinct phenomena. Characterizing nature as socially constructed is meant to be provocative because the received wisdom is so entrenched. Specifically, how nature is considered from the perspective of social construction is twofold. First, what humans understand as nature is considered as always an interpretative construct, a nature for humans. This does not mean that no nonhuman nature exists, only that what humans can know about this nature is only through their own interpretations.

The second way in which nature is considered is more novel. This is the idea, particularly among those who speak of the social *production* of nature, that humans actively construct social natures in the process of materially reproducing themselves and their societies. In this view, humans are considered not as separate from nature, influencing it from without, but rather as an active part of nature, imagining and influencing it thoroughly from within, whether in the scientific laboratory or in the process of material reproduction. In terms of the latter, cities are as much a part of natural ecosystems as the nearest estuary.

What follows is a brief consideration of the idea of the social construction of nature on the basis of this analytic; but in reality, the distinction

between those who consider nature to be interpretatively constructed and those who consider nature to be constructed by human activity is not very clear-cut, because those who take the latter view recognize that human action is driven by interpretation.

How Do We Know Nature?

The notion of the social construction of reality emerged and rapidly gained popularity amid the growing critical debate concerning the conduct of science and the activities of scientists that began in the 1960s in virtually all disciplines, including geography. This debate concerned the then prevailing image of science as a process by which an objective view of reality, or nature, could be attained via an objective or “positive” scientific method followed closely by individual scientists. This prevailing positivist image of science came under increasing attack by those who argued that the practice of science was, instead, a thoroughly social affair, both in terms of how scientists conduct their research as well as in terms of how external social influences determine the problems on which scientists work. This emerging post-positivist critique of scientific practice—hereafter called the internalist perspective—was initiated by Thomas Kuhn with his book *The Structure of Scientific Revolutions*, in which he argued that scientists always work within a worldview, a “paradigm” of largely unquestioned assumptions, which determines their view of reality. The implication of Kuhn’s argument is that scientists, regardless of the methods they use, can never have direct access to an objective reality; all that is known to them is filtered through a paradigmatic or interpretive lens. Scientists, in this respect, do not observe and passively record reality. They construct a paradigmatic version of it, which may or may not be true of reality itself.

These criticisms of the positivist conception of science were heightened since some disciplines, particularly the natural and physical sciences, were considered more scientific or objective than others because their objects of study were more conducive to the use of the scientific method. This scientism, or idealization of a certain method as the only objective method by which the real world can be understood correctly, rendered

these sciences worthy of greater support and recognition as privileged purveyors of scientific certainty about reality. If, as the social constructionists argue, these sciences do not have a privileged access to the real world, than the certainties they purvey are no better than those purveyed in the so-called soft sciences of society and culture, the practices of which are much less conducive to the use of a particularly conceived scientific method.

Other critics of positivism focused their attention on how wider social issues and activities affected the conduct of science. This externalist focus was taken by those who argued that the social influences on scientists, such as religion, class, ethnicity, gender, research-funding opportunities, and political persuasion, cannot be avoided in the conduct of science, and therefore a truly objective reality cannot be determined, regardless of which method is used in investigation. This view of science as a social practice was reinforced by the social turmoil in the streets in the 1960s, when virtually all received social truths came under attack.

The idea of the social construction of nature thus emerged from within these general critical, post-positivist perspectives. What one considers nature to be is determined by the interpretive framework within which one views it, and this framework is variously constructed both within the process of doing science and on the basis of potentially numerous other socially derived biases on the part of scientists themselves. Again, the reality of nature is therefore not found and recorded readymade but, rather, interpretively constructed by human observers.

The Construction of Invasive Species

The apparent problem of invasive species can serve as an example. Such species prosper in locations other than their native ones and often, according to some observers, wreak ecological havoc by not fitting in well with the native species. Specifically, invasive species tend to reproduce themselves faster than natives, adversely change the established relations among natives by not fitting in, and are said to be leading to lower biodiversity as they overwhelm the native natural environments by homogenizing them, as a result of proving to be more fit to survive than the

natives. On the basis of this characterization of the problem, many environmentalists argue for a concerted effort to control or curtail such invasions for the good of nature itself.

Of interest here is that this abbreviated characterization of the problem of invasive species suggests a specific interpretation of nonhuman nature. Already established nonhuman nature is privileged over change in this interpretation, or at the very least, some ecological changes are considered better than others for nature itself. But is this not simply a specific human interpretation of what is best for nonhuman nature? After all, do we not also scientifically consider nature to be in a process of constant change via evolutionary processes? Those species considered native at one time were invasive in the initial colonization phase. What makes these now nativized species more valuable or naturally appropriate than recent immigrants to the extent that some call for the complete species cleansing of the latter?

In short, if humans do not have direct noninterpretive access to the reality of nature, the way nature is represented determines not only how we know it but also our actions toward what we perceive it to be. Privileging some species as native is not a simple reflection of what is but a human value judgment that renders species that came to exist at some point in space-time more worthy of existence than those that came later. But is not the spatial migration of species the very stuff of natural evolution? The zebra mussel currently invading the U.S. Great Lakes, for example, in addition to clogging humanly constructed water intake and discharge pipes and promoting the mass extinction of native freshwater mussels, is also, via its rapid filtering process, clarifying the Lake waters and providing, via its rapid proliferation, a more diverse food supply for migratory diving ducks. Perhaps the zebra mussel is leading to a decline in local biodiversity in the short term due to its ability to outcompete the native species. Yet who is to say what will happen along these lines in the evolutionary long term, with or without human action?

Constructing Ecosystem Science

Another illustration of the social construction of nature concerns the characteristics and reality of

ecosystems, one of the fundamental concepts in the environmental sciences, including geography. The notion of an ecological system, biotic and physical, as a specifiable unit of nature dates from the 1930s and established itself as the dominant conception in the environmental sciences in the 1950s and 1960s. Yet actually defining an ecological system, let alone discovering such units as a result of empirical investigation, is fraught with difficulty. This difficulty is well elaborated in the scholarly literature and includes how to delineate the boundaries of such units, what criteria to use in defining the system, what size of system is appropriate to study, or even whether the chosen size of the investigative site itself determines what is called a system, implying a potentially unlimited number of extant ecosystems. These definitional problems translate directly into what some call a fatal problem for empirical investigation, rendering ecosystems merely subjective and therefore arbitrary, solely in the minds of observing scientists.

Nevertheless, the idea of the ecosystem eventually became hegemonic within the dominant paradigm of the environmental sciences as most scientists, and their students, operate within the normal science that accepts its facticity. Why this is the case, given the conceptual and empirical difficulties it entails, can be determined from the perspective of social construction. General systems thinking, for example, became all the rage in academia in the immediate post-World War II era, linked tightly to the emerging field of cybernetics and early computing. This rage was fueled by a technological optimism resulting from the innovations of the war effort. Systems science was cutting-edge, in this respect, as it promised a unique methodology that could conceivably model the real complexity of the natural and social world in a holistic manner. Every scientific discipline went through a phase in the 1950s and 1960s that privileged systems science as the newest, best scientific practice.

This privileging of systems science was reinforced by the new postwar, GI Bill recruits into academic science and technology disciplines with more diverse and practical views of the scientific project. Systems science, to them, was the basis for engineering the way to the solution of whatever environmental or social problem was at

hand. That systems thinking took over the environmental sciences is not a mystery within this social context.

But this is not the end of the story. Other social aspects of the 1960s and 1970s played an important part in the acceptance and growing hegemony of the ecosystem idea. These include the growing rebellion against all established norms on the part of those born after the war as well as the emerging environmental movement. Newly minted PhDs were more likely to adopt the latest methods of their respective sciences, confronting established beliefs with novelty as an indication of “progress.” Finally, ecosystem science also provided a valuable tool for the emerging environmental movement. If the goal is to “save” as much nature as possible, what better argument could there be than the “fact” that all things in nature are systematically related? That is, if one touches one part of nature adversely, all these other parts of nature will be damaged as well. Thus, if you want to save the spotted owl, the entire old-growth forest must be preserved. Indeed, such an argument has been ramped up to include the notion that the whole planet is one big natural system in increasingly bad shape because of human activity.

That there is a growing minority of scientific critics of the ecosystem approach, however, suggests that it may not be the mirror of reality that its paradigmatic adherents assert. Of interest here is that the reaction to these criticisms actually helps confirm the perspective of social construction. Reacting to what pejoratively has been called the “postmodernism” of the critics of ecosystem science, ecosystem scientists have often impugned the assumed political motives of their scientific critics. That is, such critics must be in the back pocket of developers hoping to open up more of nature to human intrusion. That it is impossible to adjudicate this scientific dispute by an “objective” look at the “facts” of the matter simply underscores the socially constructed nature of nature.

From the Construction to the Production of Nature

The idea that humans actually produce a socialized nature—as a reality, not just a conceptuality—is initially intended to underscore that humans are an active part of nature, not an external, extranatural

force that “affects” it from without. The nature of nature is thus different from this perspective. The focus here is on how human material activities produce both what we consider to be nature and the surrounding landscapes that are considered natural. An implication of this perspective is that because what humans consider to be nature and natural are only artifacts of their own material activities, they are fully historical and open to change as human material activities change over time. Nature is always social nature, in this respect, not something outside social reproduction to be merely observed, protected, saved, restored, conserved, or otherwise managed by somehow extranatural humans. Nature is what results from the various cultural and historical ways in which humans socially (re)produce both their sciences and their societies.

As in the case of social construction, there have been two, not entirely separable, ways in which this production of nature perspective has been pursued. There are those, most notably Bruno Latour and Donna Haraway, who study very closely how scientists produce nature in their laboratories as a result of their established networks of investigative methods and instruments as well as their discursive relations with other scientists. That is, from this internalist perspective, nature and the natural are brought forth or made observable only by the investigative activities of, and technologies used by, scientists in the act of doing science. Scientists, in this respect, produce what is considered nature—they do not discover it in their research. Nature is thus always a socialized, human-nonhuman, fully hybrid phenomenon and, as such, can be questioned and changed as a result of changing human interests and actions.

Another version of the social production of nature perspective emphasizes the extrascientific, social nature of this process. Expressed most directly in geography by Neil Smith and Erik Swyngedouw, this externalist version focuses on how humans appropriate, modify, and otherwise make use of nonhuman nature as a result of the particular social relations they enter into in the process of materially reproducing themselves. That these social relations of production have changed in the past and can change in the future suggests again that what is considered nature and

the natural are entirely social constructs, which can be socially deconstructed as a result of changes in these social relations. The emphasis is on the material reproduction of what can be called social natures, whereby humans and human constructions such as cities and other built infrastructures are considered as much a part of nature as the nonhuman parts. The key is that viewing nature as socially produced suggests the possibility that a different nature can be had through changes in social production. If this is so, then what are considered environmental problems are always a function of specific forms of social nature and not that of a universal “relation” between humans and a separate nonhuman realm called “nature.”

The political intent of this seemingly absurd notion of the social production of nature is clear. It is not meant to suggest that there are no nonhuman natural processes or that human reproductive activity is never limited or otherwise affected by such processes. Indeed, the overall ontological view entailed is that human and nonhuman natural processes mutually adapt to become social nature. This is an optimistic view, which considers that the so-called environmental problems, such as the tragedy of the commons, overpopulation, pollution, global warming, and so on, have everything to do with the ways in which humans actively produce social natures at both local and global scales. Solving environmental problems necessitates recognizing their source within a particular, historical form of social nature and then moving to change this latter. Environmental problems, in this view, are never absolute, the result of some universal human-nonhuman nature nexus, but, rather, always entirely relative to the form of social nature that is produced thereof. Such problems are thoroughly social and historical, and recognizing this is the first step toward their resolution by conscious human action.

SOCIAL DARWINISM

Although Charles Darwin himself never sought to apply his ideas of evolution through natural selection to the social world, numerous advocates of Darwinism selectively and erroneously applied this line of thought to the analysis of cultural relations. Thus, *The Origin of Species*, published in 1859, was enormously influential not only in the biological sciences but in the social sciences as well. The (mis)application of Darwin’s ideas to social analysis is called social Darwinism, and its effects were enormous as well as uniformly reactionary. Some of its tenets preceded Darwinism

itself, including, for example, the works of Thomas Malthus. By posing as a science, the pseudoscience of social Darwinism dismissed criticisms as unscientific. The heyday of social Darwinism occurred in late-Victorian Britain and in the United States during the Gilded Age of the late 19th century.

An important moment in the translation of Darwin’s ideas to the social world was marked by the work of the French biologist Jean Baptiste Lamarck (1744–1829), who preceded and influenced Darwin. Lamarck’s view of evolution centered on the inheritance of acquired characteristics—that is, organisms pass on characteristics that they adopt to survive in different environments. Neo-Lamarckism posited that culture is carried biologically as a “social mind”—thus discounting the notion of random chance, which played such a large role in Darwinian thought—and therefore that evolution occurred much more rapidly than via Darwinian natural selection. Social Darwinism effectively became a search for supposedly universal laws of people and their relations to nature, a view that, when coupled with place, led to notions of regions as an organic entity in which blood and territory were inseparably fused. Such a perspective was influential, for example, in late-19th- and early-20th-century cultural geography, as in the *pays* (a French word defining an area whose inhabitants share common geographical, economic, cultural, or social interests) of Vidal de la Blache.

Herbert Spencer (1820–1903), a conservative 19th-century British defender of Lamarck, who fanatically opposed all government programs to aid the poor, became the best-known advocate of social Darwinism. It was Spencer, not Darwin, who coined the term *survival of the fittest*. His work found far more favor in the United States than in Britain, where it justified and naturalized the inequities of laissez-faire capitalism. Spencer was the foremost intellectual in the late 19th century to deploy social Darwinism to legitimize the excesses and inequalities of the Gilded Age. Numerous respected intellectuals and tycoons preached that competition in the market enshrined whoever emerged on top, naturalizing the status of the wealthy as inevitable and indeed fortunate for all: Millionaires are deserving of their wealth because they are simply stronger and work harder than do the lazy poor. Not

surprisingly, social Darwinism was often invoked to justify racial and ethnic inequalities as well, and its ultimate manifestation was in the 20th-century eugenics movement, which advocated the sterilization of ethnic minorities, the handicapped, and the socially disadvantaged to weed out “undesirable” genes.

Internationally, social Darwinism became a model of the global hierarchy of societies, with the white, Western world at the top, of course. Ostensible social evolution was posited to occur in stages, a view highly conducive to the dominant interests of 19th-century imperialism: Indeed, it is unlikely that social Darwinism would ever have enjoyed much popularity were it not for its role in legitimating the Western domination of the non-West. Because race and nation were typically held to be synonymous, with white countries seen as the more advanced and civilized compared with those in Africa, Asia, and elsewhere, social Darwinism gave a scientific veneer to racist doctrines. Nineteenth-century textbook portrayals of the globe, for example, framed the Western geographical imagination around a series of continents, typically conflated with simplistic notions of race, that were hierarchically organized in terms of their alleged level of temporal progress and, thus, similarity to European and North American whites, a schema that gained respectability through appeal to various forms of social Darwinism and environmental determinism. Social Darwinism and the geopolitical view it sustained thus not only explained colonial rivalry and conquest but also legitimized it with an aura of scientific respectability.

The most famous expression of social Darwinism in geography was through Friedrich Ratzel's ideology of geopolitics, in which states are held to follow the rule of survival of the fittest, constantly needing more territory (*lebensraum*), and inevitably conflict with one another (*kulturkampf*). Ratzel conceptualized states as organic entities that grow as plants grow. He drew on social Darwinism to argue that only the fittest states would survive. Ratzel moreover posited that states go through a life cycle from amalgamations of tribes to civilizations to senescence. Thus, primitive societies are “immature”; they then become vigorous and eventually senile. His biologization of international relations explicitly

used Darwinism to naturalize geopolitics and merged perfectly with the perceived need of the Anglo-Saxon/Teutonic race to conquer and lead the world's “inferior” races. Ratzel was read with interest by Adolf Hitler, and his views contributed to the emerging Nazi doctrines of racial superiority and inferiority during the Holocaust. This perspective, which later mutated into environmental determinism, is an example of the philosophical assumption of naturalism—that is, that the physical and social worlds can be understood in the same conceptual terms.

Social Darwinism also infiltrated the first paradigm of urban structure offered by the Chicago School theorists, particularly McKenzie, which centered on the metaphor of the city as an urban jungle. For example, the displacement of one ethnic group by another in a given neighborhood was framed as a process of invasion and succession, a view that drew directly from ecological studies of how one plant species displaced another through successive stages in the evolution of ecosystems.

Ultimately, social Darwinism was discredited on numerous pragmatic and ethical grounds. The end of formal imperialism and the horrors of World War II undermined its utility in justifying oppressive social policy. Its simplistic misapplication of Darwin's ideas to the social world was criticized by biologists, many of whom pointed to the lack of significant differences in intelligence among ethnic groups or between the sexes. Social scientists pointed toward its conflation of existing social orders with what social Darwinists posited to be morally necessary (that which is must therefore always be), denying any active role for culture, consciousness, historical context, and contingency in the making of social life. Social Darwinism's “might makes right” perspective was ultimately jettisoned in an age more attuned to the social nature of inequalities, one that celebrates differences rather than condemns them in hierarchical terms.

SOCIAL FORESTRY

Social forestry belongs in the same category with terms such as community forestry, joint forest management (JFM), and farm forestry, but it is not synonymous with them. The term *social forestry* was first used by Jack Westoby in his address to the Ninth Commonwealth Forestry Congress at Delhi, India, in 1968—"Changing Objectives of Forest Management"—and subsequently at the 1978 Eighth World Forestry Congress in Jakarta, Indonesia. Influential papers heralding a change in forestry were also published by the World Bank and by the Food and Agriculture Organization of the United Nations (FAO). In this context, social forestry stands for a shift of focus in forestry in developing countries away from production-oriented and revenue generation-oriented forestry toward forestry for the needs of local users. This was later followed by a shift from centralized to decentralized forest management in the form of community forestry and JFM. In the context of India, which is the birthplace of social forestry, the term is applied in a more narrow sense to state-sponsored tree-growing programs on unused or degraded land.

In India, a social forestry program was initiated by the National Commission on Agriculture

in the 1970s, and it provided the framework for subsequent forest legislation, such as the Forest Policy of 1988, which recognized local users' rights and stated that forests were no longer to be managed for revenue generation only, and the contemporary JFM policy, which was drafted in 1990. However, Dietrich Brandis, Inspector General of Forests in India from 1864 to 1883, can be considered the first proponent of social and community forestry in India. Contrary to most members of the British Colonial Forest Service, who pursued a policy of putting forests under government control, Brandis believed in the capacity of local communities to manage their resources and advocated a parallel system of commercially important state reserves managed by the Forest Department and village forests outside of state reserves managed by farmers in collaboration with Forest Department rangers. He published a series of reports on this issue from 1868 onward, which led to a proposal to provide scope for community management of forests under the 1878 Forest Act. Brandis's proposal was rejected, however, and the 1878 Forest Act was firmly based on the principle of state monopoly over forests.

The concept of forestry for local people was resuscitated in India following popular protests against state forest policies, which started in 1904, took the form of a forest movement with labor strikes and the burning of forests in 1921, and culminated in the Chipko Movement of the 1970s against the logging of pine forests. The government of independent India, which had initially attempted to continue the policy of the British administration of maintaining or even increasing control over forests, backed down and started a process of developing policies for integration of and collaboration with local users.

The practice of social forestry in the context of India can be defined as growing trees on all land available for the purpose, especially on land outside traditional forest areas, with involvement of the local people and with a view to reduce pressure on forests and to provide a wide range of goods and services for local users, especially fuel and fodder. Tree-growing programs on unused land, such as along roadsides and reservoir walls, were pioneered by several states, for example, Gujarat and Tamil Nadu. In 1985, a National Wastelands Development Board (NWDB) was

created to coordinate tree growing on degraded or unused land on a national scale. The practice of social forestry was criticized as an attempt by the state forest departments to extend their control onto land outside their domain, but it also brought onto the scene international donors, especially the Swedish Sida, and nongovernmental organizations, which engaged in social forestry programs all over India. Social forestry programs in India were also criticized for the selection of controversial tree species such as the eucalyptus and for allowing only a limited scope for community participation.

Social forestry is often associated with terms such as *farm forestry*, *community forestry*, *participatory forestry*, and *JFM*. Farm forestry has been supported in India under social forestry programs and is an initiative to encourage or support individual farmers to grow trees on their farmland in order to meet domestic demands. Farm forestry is practiced in Nepal under the name “private forestry.”

Community forestry sprang from the same roots as social forestry. While social forestry programs in India and their various components were implemented mainly by state agencies for the benefit of local users but with only limited involvement of local users, community forestry focuses more strongly on community participation and community development through tree growing on community land, not on private land. Community forestry has been defined as involving some element of community participation in forest management and some commitment to the provision of forest products to rural people. Community forestry was particularly successful in Nepal. In India, collaboration between the state and forest protection committees was carried out under JFM, first in the state of West Bengal and later in other parts of India. While social forestry has remained associated largely with practices in India, community forestry is now practiced in many countries, especially in Asia.

SOCIAL GEOGRAPHY

Social geography is the branch of human geography that analyzes social phenomena in space, both tangible artifacts and intangible phenomena. It involves the study of a wide variety of social phenomena ranging from individual children and adults to social problems such as poverty and crime. In all instances, social geographers are interested in the ways in which space and place shape social phenomena and, in turn, how social phenomena influence the construction of places and space. This two-way relationship has been examined in diverse settings around the world and by analyzing a wide variety of social phenomena. Social geography plays a crucial role in human and physical geography, reminding us that all geographies reflect the influence of people and the social organizations within which they live. Diversity is the hallmark of contemporary social geography, which adopts many different approaches to the analysis of social phenomena. This entry outlines the major questions addressed

by social geography and, in roughly chronological order, the various ways in which geographers have viewed these topics. The emphasis is on the assumptions about people and their social relations that underpin each approach. The different research methods used within each approach are also described. The discussion ends by reviewing three current debates about the future direction of social geography.

Questions Guiding Social Geography

Social geographers have analyzed people's uneven knowledge of places, often asking them to draw maps of the world, their countries, and the cities and neighborhoods where they live. In addition to examining people's awareness of individual locations and their positions relative to each other, geographers also explore how people evaluate places, asking why one neighborhood is considered attractive while others repel or evoke indifference. Increasingly, social geographers examine the meanings that people attach to different locations by asking them where they feel at home and where they feel out of place. Investigating the social and built characteristics of public spaces where women feel unsafe at night, geographers have recommended design changes that will ensure that women as well as men are at ease in public spaces.

Different questions have motivated social geographers' studies of diverse social groups. Some geographers have studied people who live in specific neighborhoods, municipalities, and regions, while others have analyzed particular segments of society, such as the elderly, children, racial minorities, income groups, hate groups, and various occupational groups. In both cases, geographers seek to understand how space and place shape the behaviors and beliefs of and the links between people in particular groups. Attention is paid to the social ties through which information and influence are transmitted among members of a social group and their spatial patterns. At the core of many studies are questions about the ways in which space and place shape power relations among social groups.

Institutions such as government, nongovernmental organizations, ethnic and religious groups, and for-profit institutions are a third topic of interest

to social geographers, who want to understand how place shapes institutions and their social impacts and how social institutions shape space and place. For example, looking at the provision of services for psychiatric survivors, social geographers have highlighted the processes that lead to concentrations of such services in poor neighborhoods, where the housing stock is often in poor condition and residents are kept isolated, far from commercial establishments and recreational facilities. Other geographers have examined how concentrating services for marginalized groups in poor urban neighborhoods stigmatizes them.

A fourth stream of social geography examines the spatial dimensions of social problems such as poverty, crime, and homelessness. Geographers often begin by creating atlases that draw attention to the locations of social problems and the circumstances that exacerbate social problems. Some of the best-known atlases document women's experiences of violence, poverty, and oppression around the world, poverty in the United States, and the living conditions of racial minorities in specific metropolitan areas. Having described the spatial patterns of a social problem, social geographers then explore the geographical variations in the factors that cause them. For example, to understand the spatial patterns of poverty, geographers have analyzed plant closures and unemployment rates as well as geographical variations in welfare policies.

History of Social Geography

The diverse body of research currently undertaken under the rubric of social geography has a long history. The beginning of social geography is often attributed to Charles Booth, who studied poverty in London between 1886 and 1903. Booth carefully documented the incidence of poverty in London in maps that survive to this day. Turning to the causes of poverty, Booth examined how occupation was related to income and how the activities of charitable and religious organizations and local governments influenced the living conditions of the poor. He concluded by proposing policies to mitigate poverty. Since the production of Booth's maps and reports, social geographers have investigated the spatial patterns of social phenomena and their causes using

numerous philosophical, theoretical, and methodological approaches.

To understand urban life, social geographers delineated natural areas with homogeneous social and built characteristics and clearly identifiable boundaries. In many American cities, geographers and sociologists identified a central business district, the commercial heart of the urban area, surrounded by a zone in transition where residential land was being converted to industrial use. Suburban housing radiated out from the zone of transition, with the newest housing located on the urban-rural fringe. As land uses changed, the social characteristics of residents in each zone also changed. The ecological approach encouraged geographers to recognize and describe diverse urban neighborhoods; however, it paid little attention to the processes shaping the spatial patterns. It was assumed that the housing market invariably segregated people on the basis of income, household type, and ethnic background. Few scholars asked why housing should be allocated on the basis of ability to pay or how income was distributed among households.

Responding to criticisms that social geography was descriptive rather than explanatory, three alternative approaches to social geography emerged: the first examining individual decision making, the second focusing on the meanings that people attribute to places, and the third emphasizing how the built and social environments are shaped by capitalism and, in turn, shape capitalism. Although the three approaches came to prominence in roughly chronological order, each has deep roots in social geography, and each has persisted into the present.

The Behavioral Approach

The behavioral approach aimed to develop mathematical models that would predict people's spatial behavior. Behavioral geographers analyzed how people decided among alternative locations, examining awareness of alternatives, their evaluation, and the decision processes by which people selected one alternative over others. Peter Gould showed that children's geographical knowledge of the world centered on their neighborhoods, towns, and countries of residence. Distant places were less likely to be known, and even if known, they

were located inaccurately. The initial mental map studies are precursors of the sophisticated analyses of wayfinding that now dominate the literature.

Beginning from the microeconomic assumption that people are rational decision makers interested in maximizing the utility of their decisions and minimizing the time, effort, and cost invested in them, geographers studied how people choose among competing locations to live, how they travel on a daily basis, and how they plan shopping trips. Studies of residential decisions confirmed that many decisions are based on incomplete information that is spatially biased. When looking for a place to live, most of us only consider a few neighborhoods. Realtors reinforce spatial biases by steering clients to vacancies in areas already dominated by people from the same social backgrounds, often reinforcing the segregation of minority groups, age groups, and occupational groups. Residential decisions are also influenced by the available housing. As housing prices rise, people abandon their plans to relocate, settling for unsatisfactory housing within their price range. The emergence of large numbers of blocked movers in areas with rapidly increasing housing prices revealed the shortcomings of the behavioral approach, which did not take account of people's subjectivity and the social, political, and cultural constraints on individual decisions. In response, many social geographers turned to humanistic and structural approaches.

Humanistic Approaches

Humanistic approaches in social geography pay attention to the meanings that people attach to locations. Harking back to earlier assertions that social geography goes beyond documentation of the spatial patterns of artifacts, humanistic geographers evaluate how beliefs about locations shape places and how places shape people's beliefs and behaviors. Humanistic geographers now investigate the emotions that places inspire, exploring how different people feel about a single place or how one group of people feels about different places. Home has been the focus of much of this research as geographers have investigated what it means for different social groups to be at home and how the meaning of home changes over our lifetimes.

With its attention on how people are represented and how they identify themselves, the humanistic approach to behavioral geography has many parallels with cultural geography. Adopting a subjective perspective, humanistic geographers explore the discourses that different people use to describe places. By analyzing text and visual representations as well as descriptions of people's behaviors and opinions, humanistic geographers aim for an empathetic understanding of place. In a pioneering study in Philadelphia, David Ley compared the meanings attached to a poor African American neighborhood by residents and outsiders, highlighting how the positive views of residents contrasted with the negative opinions and beliefs of government officials and other people living outside the neighborhood.

Structuralist Approaches

In parallel with the resurgence of humanistic approaches, social geography was transformed by historical-materialist approaches grounded in Marxist theory. Focusing on social inequality and the processes that give rise to it, geographers explored how capitalism molds social class and inequality. Although historical materialism was new, the critical stance has a long history in social geography. In the 1960s, social geographers had studied the geographical patterns and causes of social inequality through projects such as the Detroit Expedition, which documented racial inequality in all aspects of everyday life in the city of Detroit. Other geographers intervened in efforts to desegregate schools by publicizing the unequal expenditures on minority students and the unfair burden that many busing proposals imposed on them. In his pathbreaking book *Social Justice and the City*, David Harvey drew attention to Marxist theory as a coherent theoretical basis for structural approaches to social geography. His analysis demonstrated how contemporary geographies are shaped by capitalism and how space is fundamental to contemporary capitalism, a theme Harvey and others have continued to explore in their attempts to rewrite Marxist theory from a geographical perspective.

Geographers working within a Marxist approach have sought to uncover the local contingencies that frame the impacts of capitalism.

They have explored the past and present geographies of production, documenting how capitalism is shaped by local circumstances and the layers of investment in different means of production that shape the way capitalism operates in different places. The role of the state in the production and maintenance of urban inequality has also been a recurring theme.

The diverse viewpoints that characterize social geography are the basis of lively debates, illustrated by the competing explanations for the revival of residential areas in many North American and Western European cities, where professionals have renovated housing vacated by working-class families since the 1980s. Historical-materialist geographers emphasized that renewal was sparked by the undervaluation of property in central neighborhoods. Humanistic geographers argued that growing numbers of professionals were seeking convenient places to live in, near jobs and urban amenities. Although economic change underpins both explanations of gentrification, one emphasizes changes in property values, while the other puts more weight on the emergence of a new occupational group seeking an urban and urbane lifestyle. As differences of opinion concerning gentrification were debated in the pages of scholarly journals, the distances between the three approaches to social geography increased and hardened.

Recent Developments

In the 1990s, new subfields of social geography challenged the boundaries between the three approaches to social geography, raising questions about the theoretical basis of social geography and the associated research methods. Feminist geography has transformed much of social geography. With the goal of reducing women's oppression and redressing the power imbalance between men and women, geographers have explored the connections between gender and geography. Moving well beyond their initial comparisons of the spatial patterns of men and women, feminist geographers now highlight how our ideas about gender shape people's behaviors and attachments to place. Variations in these ideas and behaviors across neighborhoods, cities, regions, and countries have been the focus of much research that

illuminates the social construction of femininity and masculinity in different settings. Feminist geographers have enriched our understanding of gender inequality by studying the geographical relations between home and workplace. In Worcester, Massachusetts, Hanson and Pratt showed that the occupational segmentation of women was inherently geographically influenced by the spatial relations between home and workplace.

As international migration has transformed the ethnic and racial composition of cities around the world, social geographers have renewed their analysis of racialization, ethnicity, and segregation. Recent studies have explored multiethnic neighborhoods, neighborhood effects on minorities, and the evolving geographies of religious minorities. Geographers have examined how religious minorities lay claim to public space, the reasons for and impacts of residential concentration on religious minorities, and the contested links between religious identity and place. Their findings underscore the complex geographies of religious affiliation, a welcome reminder that no one is or should be defined solely on the basis of his or her religion.

A third stream of social geography abandons the pretense of universal heterosexuality to explore how sexuality and sexual orientation influence people's use of space, their attachment to place, and their sense of belonging in different spaces. Claims to space by gays, lesbians, and transsexual and bisexual people are an integral aspect of their struggle for recognition and equal rights. Gays have colonized entire neighborhoods, transforming them into vibrant centers of gay culture, while lesbians, transsexuals, and bisexuals have demanded the right to participate in public events such as parades and festivals. Recent research emphasizes how different aspects of identity intersect in people's claims to space. Lesbians' interpretations of public and private spaces are shaped as much by their gender and social class as by their sexual orientation. Sexuality studies have exposed social geographers to fertile theoretical arguments about embodiment and the performance of identities, encouraging them to explore new topics such as motherhood and fatherhood.

As social geographers acknowledge the complexity inherent in people's social identities and behaviors, more attention is also being paid to

the geographies of children and youth. Social geographers are examining how the experiences of childhood and youth are framed differently by other dimensions of identity such as social class, race, and religion in specific places. The impact of the Internet on the spatial patterns of children's and youth's social networks and activities is another topic attracting researchers. Parents' use of space to discipline and control children and youth has confirmed that social constructions of femininity and masculinity are inherently spatial.

Current Issues

Since the publication of Harvey's *Social Justice and the City* in 1973, social geographers have debated the roles of social structures and individual agency in explaining contemporary social geographies. Many favor the explanatory power of a structural perspective, as exemplified by the incorporation of Marxist theory in social geography. Drawing on the humanistic and behavioral traditions, others place more weight on individual agency to explain spatial behavior. Growing numbers of geographers now acknowledge the explanatory power of social and spatial structures that constrain individual actions in the short run, while recognizing that individuals transform social and spatial structures in the long run. Although sometimes labeled as eclecticism, this perspective provides a dynamic framework for examining how people's behavior is shaped by space and place in the short term and how people in turn change places and spaces in the long run.

Currently, there is also a renewed appreciation of the merits of applied and theoretical research in contemporary social geography. Some had objected to the emphasis on theory and the interpretation of texts and visual representations that accompanied the cultural turn in social geography. They argued that social geography was losing its relevance to contemporary social issues and public policy. An accommodation is now emerging in which many social geographers recognize that theoretical research and empirical research fruitfully inform each other.

Several people have recommended that geographers abandon social geography to concentrate on emerging subfields such as feminist geography, geographies of children and youth, and

geographies of sexuality. The debate is fueled by the blurring boundaries of social geography. Influenced by the cultural turn in human geography, social geographers are paying more attention to people's cultural backgrounds and using unobtrusive methods and discourse analysis to explore how culture shapes sociospatial relations. Acknowledging that economic relationships are one of the main sources of social power, they are also examining in detail the changing nature of paid work, the relations between paid and unpaid work, and the intersecting effects of gender, race, and class on individual work experiences. With its history of multiple approaches and subfields, debates about the boundaries of social geography are likely to continue. Despite these tensions, social geography will persist because of the integral links between place, space, and social relations. Labels may change, the theoretical underpinnings will evolve, but the interest in how geography shapes social relations and, in turn, how social relations shape place and space will persist.

SOCIALISM AND GEOGRAPHY

Socialism is a concept that has been subjected to many interpretations. Such diversity in the use of the term *socialism* has led to the creation of different bodies of knowledge. Socialist theories, writings, ideas, and beliefs generally explain, seek, and advocate social justice and equality. In other words, socialism is seen as an instrument to attain a better and fairer society; social justice and equality are achievable through a social system based on common ownership of the means of production and the equitable spatial distribution of wealth. Therefore, socialism is a system of thought and practice whose ideas are contrary to the system of material accumulation, concentration, and exploitation found under capitalism.

Forms of Socialism

As a result of the diverse uses of the term *socialism*, it has often been confused with the term *communism*. Commonly, these two terms have been considered synonymous: They have both been

used to describe a social system structured contrary to the logic of capitalism, namely, a system in which the means of production are not privately owned and material interests do not prevail over the common interest. In practical terms, both socialism and communism share this advocacy of the common interest; both bodies of knowledge critique the social and territorial injustices of capitalism. Yet regardless of their similarities, socialism and communism are not synonymous. Socialism is a necessary precondition to achieving full communism, but there is a fundamental difference between socialism and communism. The essential distinction between the two concepts lies in the difference between common ownership and state ownership. In socialism, social justice and equality, and thus a better and fairer society, are realized through a social system based on common (i.e., public) ownership of the means of production. Communism aims to consolidate socialism through state ownership of the means of production. Therefore, communism represents a new form of society where human beings overcome material constraints. In that context, communism is the maximum expression of socialism, and in classical Marxist ideology, socialism serves as the transition to communism.

However, the diverse use of the term *socialism* not only has generated a blurred line between socialism and communism but has also caused a division within socialist theories, writings, ideas, and beliefs. The most important of these socialist divisions are utopian socialism, democratic socialism, Leninist socialism, and Marxist socialism. In utopian socialism, there is unity between the individual subject and the collective object. This interpretation of socialism is based on the principle of cooperation. The result of utopian socialism is not only a social system in which the means of production are collectively owned but also a system in which social and economic life is driven by the collective.

On the other hand, democratic socialism tries to find a common ground between revolution and electoral means. Essentially, this interpretation of socialism aims to reform capitalism through state regulations that work to neutralize or remove the social injustices produced by capitalism. In other words, democratic socialism does not seek to completely and radically eradicate capitalism but

rather to reform it and make it more socially sensitive. Social justice can be attained through state welfare policies that incorporate a mixed economy with elements of both socialism and capitalism, as is found in many European welfare states, particularly in Scandinavia.

Leninist socialism, in contrast, rejects all forms of capitalism, reformed or not. This type of socialism argues that social justice, and thus a better and fairer form of society, can only be achieved through social revolutionary consciousness. Such revolutionary consciousness will lead to the overthrow of the capitalist system by force and the seizure of power on behalf of the proletariat. In Leninist socialism, the means of production are controlled by the state; however, the dominant institution is the Communist Party. This party, through democratic centralism or strict and disciplined organization, is the institution where all decisions are made. Therefore, the party uses the powers of the state as an instrument to achieve a new form of society and to help the collective reach the highest level of social justice and equality—that is, communism.

Last, Marxist socialism revolves around the proletariat generated by the capitalist production process. In Marxist socialism, the means of production are collectively owned, and social life is organized through central planning. Socialism, from this perspective, is a necessity to end class struggle and therefore obtain social justice and equality. However, in the case of Marxist socialism, it is believed that socialism will come through a proletarian-led revolution and the implementation of the dictatorship of the proletariat. Such a revolution would eradicate the capitalist system of accumulation and therefore would also eradicate poverty, exploitation, and social injustices. However, the revolution of the proletariat will not come about until society gains a consciousness of class.

Socialism and Geographical Discourse

The bodies of knowledge that deal with socialism have been present throughout the history of the discipline of geography. Geographers have always been interested in understanding how space and society work. In that context, socialist ideas have been used in geography as a framework for understanding spatial phenomena over time and their

social outcomes. These socialist ideas have also been used by geographers to question and challenge the traditionally conservative orientation of geography.

Socialism formally came into geographical discourse with the development of critical human geography and its critique of the positivism introduced to geography by the quantitative revolution. Yet socialism was institutionalized in geography with the emergence, during the 1970s and 1980s, of radical geography. This new school of thought argued that positivism was not useful because it failed to provide alternatives or solutions to the social illness produced by the system of capitalist accumulation. Therefore, radical geographers sought to counter the positivist quantitative methods with techniques drawn from socialist theories.

Radical geography built on concerns for poverty, racism, and segregation. Radical geographers were interested in a proactive discipline capable of shaping society, not just studying it. In other words, geographers saw radical geography not only as a way to understand spatial and socioeconomic phenomena but also as an opportunity to provide alternatives and solutions to current social inequalities. In that context, the socioeconomic inequities associated with spatial inequalities are at the center of the radical geographers' agenda. Therefore, the current developments in radical geography have been focusing on racial and ethnic spatial inequalities with respect to housing, access to services and employment opportunities, and exposure to environmental pollution and related public health outcomes. In that sense, academic work developed from a radical geographical perspective seeks to address current social justice issues. Such academic work has been mainly produced through political geography, urban geography, and economic geography.

As a consequence of the radical turn, geographers developed a Marxist analysis to not only understand but also improve society. This Marxist analysis draws on the concept of historical materialism to illustrate how in the capitalist system the spatial distribution of social subjects is controlled by the means of production. The main objective of this Marxist geographical perspective was to find alternative models to alleviate, if not eradicate, poverty and exploitation in capitalist societies. Therefore, Marxist geographers are

interested in the geographies of social, economic, and political inequalities that they saw around them. In their view, such inequalities are produced by a system of capitalist accumulation and the markets that embody such a system. Consequently, Marxist geographers seek to understand the processes of capitalist accumulation, in order to explain the fundamental factors involved in the dynamics of class, while also examining the processes by which economic landscapes are made.

Marxist geography gained impetus with the current expansion in the scope, volume, and velocity of the flows of goods, services, capital, knowledge, and people across borders. For Marxist geographers, those globalizing forces are intimately tied up with the rise and expansion of the capitalist system. Therefore, such globalizing processes act as the validation of Marxist geography and its analysis of how the capitalist system of accumulation produces poverty and exploitation. In this context, Marxist geographers question the global forces that bring markets and capital together while at the same time increasing the socioeconomic gap between the poorest and richest. Consequently, for the Marxist geographer, globalization reflects the true nature of the capitalist system of accumulation as it fosters increased social, economic, political, and cultural unevenness across space, therefore creating unevenness.

The belief that the global capitalist economic system has divided the globe between rich and poor countries provided the foundation for socialist geographers, especially Marxist geographers, to expand and develop some theories of economic development. From this perspective, socialist geographers argued that unequal capitalist relations not only have prevented poor countries from obtaining proper development but have also generated underdevelopment. Therefore, poverty and inequality are seen as a direct consequence of the exploitation caused by the capitalist economic system. These ideas are based on the Marxist analysis of inequalities, which argues that such underdevelopment is a direct result of the ways in which poor countries are integrated into the world system.

The expansion and development of these theories of economic development follow the proactive nature of socialist geography. Therefore, to not only explain but also provide alternatives and solutions to the social illness produced by the

system of capitalist accumulation, especially the problem of underdevelopment, geographers also make use of theories that explain colonialism and neocolonialism, such as Lenin's theory of imperialism. The Leninist approach saw imperialism as the highest stage of the capitalist economic system, which uses the state machinery to colonize and exploit other countries. Therefore, it is argued, the historical development of the capitalist system has produced underdevelopment in the colonized countries and continues to do so through neocolonization.

Socialism has greatly influenced the development of geography. Socialist theories, writings, ideas, and beliefs were used by geographers seeking a better understanding of the socioeconomic inequities associated with spatial inequalities. Geographers also saw the relationship between socialism and geography as an opportunity to provide alternatives and solutions to such social inequalities. Currently, socialist influences continue to grow in geography as geographers are exploring and developing new methods of analysis to both understand and improve society.

SOCIAL JUSTICE

Social justice is an intellectual and practical response to Cervantes's observation in *Don Quixote* that "there are only two kinds of families in the world . . . The *Haves* and the *Have-Nots*." Of course, a concern for social justice is more than simply acknowledging the inequalities of life. The following three questions outline a discussion about social justice. First, how has social justice been theorized as a moral question? This approach situates social justice as a philosophical ideal. Second, how do we measure social justice? This view positions social justice as a field of scientific inquiry defined in opposition to social inequality and prejudice. Third, what can be done about human suffering? Here, social justice is a call to action. These three questions provide a framework for defining social justice.

Social Justice as a Philosophical Ideal

Human societies depend on social norms and laws to regulate human behavior. When people break laws, they usually face repercussions. Criminal justice is served when punishment is meted out in proportion to the crime that was willfully committed. *Social* justice, on the other hand, questions why people suffer even though they have done nothing wrong. The implication is that we need to abide by universal standards of fairness and basic human rights.

Philosophers have discussed basic human rights for millennia. Plato, writing more than 2,000 years ago, said that Greek citizens should deal with foreigners as Greeks deal with one another. The Roman philosopher Cicero argued that every person should be valued as a citizen of the whole universe. The notion that we should treat others

as we would have them treat us can also be found in many foundational religious texts, including the Bible and the Koran.

Leaping forward to the 18th century, the call for universal human rights was enshrined by Thomas Jefferson in the U.S. Declaration of Independence. Jefferson wrote that all Americans had basic rights to “life, liberty and the pursuit of happiness.” But this represents only a limited “equality of opportunity,” where individual freedoms allow people to succeed in life but provide no guarantee that success will occur. Freedom of opportunity only provides a legal framework for equality before the law. It says nothing about equality of outcomes, where people might expect freedom from hunger, poverty, or violence.

Social Justice as Social Scientific Inquiry

Given the geographical variations in the distribution of natural resources, the randomness of natural disasters, and other factors beyond human control that create social inequality, some philosophers argue that social justice must also focus on equality of outcomes. Social justice is therefore an effort to strike a balance between individual rights and the common good, which we might define as community rights.

To gauge whether equality of outcomes has been achieved, measurements must be taken. One way to compare regional inequalities is to focus on quantitative income or poverty statistics. More sophisticated measures such as the United Nations Human Development Index (HDI) include literacy rates, infant mortality rates, and life expectancy. The HDI recognizes that simply using income or economic output measures, such as the gross national product, to compare regional inequality hides the fact that countries with large economies may have large internal economic disparities or restrictions on human rights.

Social Justice as Call to Action

Marx wrote in *Theses on Feuerbach* that “philosophers have only interpreted the world, the point is to change it.” This call to action, which has been subsequently echoed by many geographers, challenges advocates of social justice to connect philosophical musings with concrete strategies to

reduce social inequality. Two main strategies have been used to reduce inequality of outcomes. The first approach accepts that despite what the Declaration of Independence says, there is no “equality of opportunity.” Long-standing racial and gender prejudices prevent some people from gaining equal access to education and other means of social advancement. To remediate the inequality of opportunity, some countries have implemented “affirmative action” programs, which attempt to increase the chances that minorities and women will gain admission into high-quality schools or get well-paying jobs. This strategy assumes that the inequality of outcomes can be decreased by reducing the inequality of opportunity.

The second approach to achieving social justice attempts to redistribute income away from wealthy social sectors and regions to areas where poverty rates are higher than some benchmark average. The redistribution of wealth is a direct acknowledgment that socioeconomic inequality is an inherently geographical problem. Hence, social justice is an attempt to use universal principles of fairness to address regionally variable problems. Martin Luther King Jr. recognized it as such when he said, “Injustice anywhere is a threat to justice everywhere.”

Because social justice is simultaneously a philosophical ideal, a field of scholarly inquiry, and a call to action, it is more effectively defined as a constellation of lofty ideas and concrete strategies. Social workers at the University of California School for Social Welfare nicely captured this complexity when they defined social justice as a process

which (1) seeks fair (re)distribution of resources, opportunities, and responsibilities; (2) challenges the roots of oppression and injustice; (3) empowers all people to exercise self-determination and realize their full potential; (4) and builds social solidarity and community capacity for collaborative action.

SOCIAL MOVEMENTS

Social movements are sustained, organized forms of collective action that strive to bring about social or political change. Typically originating in civil society, they seek to change the policies and actions of the state, the practices of corporations, or the organization of society generally. Like all social relations, social movements are spatially constituted. Social movements mobilize and operate in a spatial context, are themselves spatially constituted by actors both internal and external to social movement organizations, and seek to alter sociospatial power relations.

There has been an explosion of geographical research on social movements since the late 1980s, incorporating a variety of geographic concepts. Much of the early research focused on the place-based constitution of social movements. John Agnew and R. J. Johnston argued for an understanding of politics that shifts analytical focus away from the nation-state, emphasizing instead the central importance of place-based social relations. Much of the contemporary research is rooted in Agnew's conception of place, consisting of three dimensions: (1) locale—the institutional and informal settings in which social relations are constituted, (2) location—the geographical areas and scales encompassing the settings of social relations, and (3) sense of place—the local structure of feeling. Agnew's tripartite conception underscores the fact that place-based social relations are

always material and meaningful, constituted through processes that may range in scale from the local to the global.

The centrality of the local-global problematic to social struggle is highlighted by David Harvey, who, drawing from Raymond Williams's notion of "militant particularism," argues that "ideals forged out of the affirmative experience of solidarities in one place get generalized and universalized as a model of a new form of society" (p. 32). How, and whether, locally forged ideals and solidarities become generalized has been a matter of some contention among social movement scholars.

Agnew's work suggests two different but complementary ways of thinking about how place-based social struggles relate to broader geographies. On the one hand, Agnew (1987) suggests a network approach focusing on "the 'paths' and 'projects' of everyday life, to use the language of time-geography, [which] provide the practical 'glue' for place in [all] three senses" (p. 28). On the other hand, he finds that "extensive fields of mediated interaction [must be understood as] managed by institutions and organizations" (Agnew, 1996, p. 131) with "hierarchical (and non-hierarchical) 'funneling' of stimuli across geographical scales . . . coming together in places where micro (localized) and macro (wide-ranging) processes of social structuration are jointly mediated" (Agnew, 1996, p. 132). Agnew clearly recognizes the importance of networks and scales, as well as structure and agency, in the constitution of place-based social struggle.

In one of the earliest in-depth geographical analyses of social movement mobilization, Paul Routledge (2003) shows how social movements in South Asia are strongly shaped through place-specific "circumstances, constraints, and opportunities" (p. 21) and how sense of place and place-based network relationships are key to understanding their dynamics. Routledge continues to explore the connection between networks and mobilization in his more recent work, examining the ways in which network strategies can build communication, solidarity, and support across scales and among diverse places. In a similar vein, Featherstone (2003) demonstrates that networked relationships among place-based struggles are to be understood as "generative, as

actively shaping political identities, rather than merely bringing together different movements around ‘common interests’” (p. 405).

While some scholars focus on the construction of the networked relationships of social movement agents, others place greater emphasis on the construction of institutional and state frameworks that both enable and constrain those agents. Andy Herod, for example, examines the scale-shifting strategies labor unions and corporations pursue to gain advantage in regional contract negotiations. Byron Miller, examining the peace movement, analyzes the scalar shifts in the political opportunity structures of the state and the implications of those shifts for mobilization strategy. Kevin Cox addresses the differing degrees of local dependence of political actors and the contingent nature of scales of political engagement. Virtually the entire scale literature conceptualizes scale as dynamic and itself an object of struggle.

Both representational and material notions of space are required to understand the mobilization of social movements. Deborah Martin, for example, addresses representational practices integral to the construction of place-based collective action frames, while Nicholls (2008) shows how material social practices in cities function as incubators of network relationships. The geographic constitution of representational and material social practices shapes relationships of trust, rationalities, and affective bonds, in turn affecting the very ability and propensity of agents to engage in collective action.

While some social movement scholars have tended to focus on particular notions of spatiality, most recognize the significance of multiple forms of spatiality. Indeed, after a period of some debate, it appears that geographically oriented social movement scholars may be moving toward an explicit recognition of multiple spatialities—for example, place, networks, scale—and the ways in which they intertwine.

SOIL CONSERVATION

Soil conservation refers to the actions that humans undertake to ameliorate the effects of accelerated erosion caused by the clearing of vegetation for agriculture or for other types of human activity. Whenever humans clear a new environment of its protective vegetation cover, the soil is exposed to an increase in the erosional effects of rain, flowing water, and wind. If these processes of accelerated soil loss continue

unabated, it can result in decreased soil productivity and diminishment of the soil resource, sometimes to the point of field abandonment. Indirect effects include siltation of streams and water bodies, which can increase the impacts of floods and disrupt waterborne transportation. However, there is much that humans can do to mitigate the impacts of accelerated erosion.

Soil Conservation Systems

Over the centuries, human societies have devised several soil conservation methods, which fall into one of two general categories: (1) mechanical methods or (2) agronomic methods. Mechanical conservation methods involve modifying the slope geometry or making micromodifications within the field. Agronomic conservation methods use plants to protect the soil from the effects of rain splash and runoff or to improve the soil's ability to resist erosive forces. Mechanical and agronomic soil conservation systems are not mutually exclusive, and the two are commonly used in combination (see conservation system photo).

Mechanical Methods

One simple mechanical soil conservation technique involves placing logs behind field stumps, a method that is often used when a field is newly cleared from forest. Another simple means of erosion control involves placing logs or rocks across small gullies or streambeds to trap

Terraces: (A) bench and (B) platform (tree)

Source: Author.

sediments and create workable farm plots. These “check dams” also help harvest rainwater in arid regions or in regions with highly seasonal rainfall patterns.

Terraces involve modifying a sloping surface to reduce the flow of water over the surface, to provide a deeper soil in areas where soils are otherwise too thin for crop production, or to encourage water infiltration. Terraces can take many forms, which include sloping terraces, bench terraces, step terraces, and platform terraces (see terrace photos). Terraces, especially bench terraces, generally involve moving large amounts of materials, and thus, they are only recommended when conditions favor their use over other less labor- and time-intensive methods of soil conservation.

Other mechanical conservation systems involve less initial time and labor inputs than terraces, but they are effective only under the right conditions. One widely used technique is the construction of narrow ridges along the contour. In the United States, this technique is referred to as contour plowing, but Guatemalan farmers construct similar features, called *surcos*, by hand using a short-handled, broad-bladed hoe called an *azadón* (see contour ridges photo).

Ditches can also be constructed to divert water off fields or to collect sediments and encourage infiltration of runoff water. Diversion ditches and storm water drains are designed to divert runoff from field surfaces into open surface drains or grass-lined waterways at field edges. Infiltration ditches trap runoff and allow entrained sediment to settle out, as runoff water infiltrates into the soil rather than running downslope.

Contour ridges planted with wheat and maize

Beans intercropped with maize (corn)

Source: Author.

Agronomic Methods

Agronomic conservation methods rely on the ability of plant cover to reduce soil erosion. The inclusion of organic matter in the soil enhances the effect of soil aggregation in soils that contain

This conservation system combines both mechanical (diversion ditches and grass-lined waterways) and agronomic methods (contour grass strips) of soil erosion control.

Source: Author.

clays, due to organic matter's tendency to bind with clay particles. These aggregates are more resistant to raindrop impact and splash erosion and help form cloddy surfaces, which serve to improve infiltration rates and to slow runoff velocity. Organic matter also provides soils with increased water storage capacity, which reduces the amount of runoff. Plant remains and leaf litter on the surface help disperse the kinetic energy of raindrop impacts and impede the flow of water over the surface. Living vegetation also reduces erosion by intercepting raindrops, impeding overland flow, and anchoring soil particles. Row crops generally provide the least amount of plant cover, especially during the early stages of crop growth. Grasses and permanent crops such as trees and shrubs generally provide the greatest amount of plant cover.

Cultural soil conservation measures include planting cover crops, intercropping, conservation tillage, and agroforestry. Cover crops are grown during the off-season, often as winter annuals, and then plowed in after harvest to form a green manure. Commonly used cover crops in the United States include rye, oats, hairy vetch, sweet clover, and lucerne. Intercropping (see photo) involves planting more than one crop in

the same field or plot. In Guatemala, farmers usually plant beans and squash in their *milpa* (maize) plots and may also plant several other crops, including beets, radishes, and broad beans, for family use. Intercropping and cover crops help reduce erosion by minimizing the amount of exposed ground surface.

Conservation tillage involves leaving residue from the previous year's crop as surface mulch. The residues help minimize the detachment of soil particles by rain splash, slow overland flow, and improve the organic matter content of the upper topsoil, all of which serve to reduce soil losses. Minimum-tillage and no-till systems also help reduce soil loss by reducing the disturbance of upper soil layers, which can break down soil aggregates over time.

Strip cropping involves growing row crops and protection-effective crops in alternating strips along the contour or perpendicular to the dominant wind direction. This approach lowers the overall erosion on a field by limiting the highest erosion risk to row crops. Soil removed from these strips is usually trapped in the next strip downslope or downwind. The conservation strips are usually planted next to a leguminous or grass crop that provides a high proportion of plant

Ancient stone-faced terraces on Island of the Sun, Lake Titicaca, Andean South America

Source: Author.

cover. These strips can be rotated, although permanent grass strips 2 to 4 meters wide are usually retained on steeper slopes (see conservation system photo).

Strip cropping falls within a larger class of conservation systems that has become known as agroforestry. Agroforestry is not actually forestry but a form of conservation agriculture that involves interplanting of trees or permanent crops with annual crops. Although the term is relatively new, small farmers throughout the world have been practicing some form of agroforestry for centuries. Farmers who practice swidden, or long-fallow slash-and-burn agriculture, in Africa and Latin America have been known to plant as many as 40 different annual and permanent crops in plots as small as one fifth of a hectare. Farmers in the Guatemalan highlands often plant coffee seedlings and bananas among their milpa crops, which they continue to plant until the shade from the tree crops begins to affect the growth of the other crops. Most agroforestry systems promoted by agricultural development agencies follow some variation on strip cropping or intercropping and may combine elements of both.

History and Geography of Soil Conservation

The history of soil conservation is probably as long as the history of accelerated soil erosion. Many societies around the world have used various conservation techniques, especially on hillsides that are prone to high levels of soil erosion. In his travels around the Mediterranean Basin in the late 1930s, Walter Clay Lowdermilk documented terraces that had been used for at least 2,000 yrs. (years) in Israel, Jordan, Lebanon, North Africa, Italy, and France. In the Americas, terraces have been used on hillsides by the Mesoamerican (Central Mexico to Northern Central America) and Andean civilizations for at least 1,500 yrs., perhaps longer (see Lake Titicaca photo). Extensive terrace systems have also been in place for many centuries in China, the Philippines, and the Pacific Island realms.

The United States has long been at the forefront of research on the erosion process and of studies on the effectiveness of various soil conservation practices. The period from 1890 to 1933 is considered the era of the first great conservation movement in the United States, and there is evidence that a less coherent soil conservation

movement was beginning to develop much earlier. Among its proponents were luminaries such as Thomas Jefferson, James Madison, and George Perkins Marsh. Madison lectured on the importance of agricultural improvement, including the benefits of contour plowing in reducing the impacts of soil erosion, and the importance of manures for maintaining soil fertility. Contour plowing is said to have been introduced in Mississippi by a planter friend of Thomas Jefferson at the latter's behest.

From these early beginnings, the practice of soil conservation in the United States increased from the 1850s until the first decade of the 20th century, when the U.S. Department of Agriculture (USDA) declared an official policy of land protection. Over the next three decades, field experiments were established to study the effects of erosion and the effectiveness of various soil conservation techniques, including the importance of plant cover in reducing rain splash erosion, which is a major agent contributing to the detachment of soil particles and their subsequent entrainment in runoff.

Other countries have followed this lead and established national programs designed to test the relevance of work conducted in the United States under other conditions, especially in the tropics, where soil erosion is of major concern. International agencies such as the Food and Agriculture Organization of the United Nations (FAO), the United Nations Environment Programme (UNEP), and the United Nations Educational, Scientific and Cultural Organization (UNESCO) have also contributed to the effort to decrease erosion, especially in developing regions. Several international erosion research stations sponsored by institutions such as the International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) in India, the International Center for Research in Agriculture (ICRAF) in Kenya, and the Centro Agronómico Tropical de Investigación y Enseñanza (CATIE) in Costa Rica are involved in multinational research on erosion and the effectiveness of soil conservation systems.

Challenges to the Implementation of Soil Conservation

While soil conservation can do much to mitigate the effects of accelerated erosion, widespread

implementation of soil conservation practices faces many challenges. While most farmers are aware of soil erosion's consequences, and of soil conservation's benefits, the effects of both are generally incremental, while labor and capital costs are often incurred at the outset. Certain soil conservation methods, such as terraces and contour grass strips, can have short-term impacts on crop productivity due to decreases in planting surface, shading, or competition for nutrients. Farmers who do not own the land they cultivate or whose landholdings are marginal for supporting their families are less likely to invest capital, labor, or space if there is a high likelihood that they will lose access to the land or that crop production will be adversely affected. Many developing countries lack the capital to invest in national conservation programs. Political instability also hinders farmers' efforts toward agricultural improvement and reduces the interactions between farmers and conservation agents.

SOIL DEGRADATION

Soil degradation is the alteration of one or more soil properties due to human or natural causes that results in a lowered performance of a soil for a specific function. The term *soil degradation* is also used to describe alteration of the soil properties associated with a soil's natural or inherent set of physical, chemical, and biological properties. Soil degradation may be a temporary condition or a permanent state, depending on the severity of the degradation and the resilience of the soil to being restored to a functional level for a specific purpose or to its natural inherent state through improved management and/or changes to physical variables (e.g., end of a drought period).

Soil erosion is an example of a soil-degradative process and is often considered to be a temporary

condition (see photo). Erosion may be minimized through alteration of land management practices to slow erosion processes and allow the degraded soil properties associated with soil loss to become restored (e.g., the reestablishment of topsoil).

The U.S. Soil Erosion Service, predecessor to the Soil Conservation Service and now the Natural Resources Conservation Service, identified the degradative effects that the intensive agricultural management practices of the early part of the 20th century were having on the rates of soil erosion in the Great Plains region. High levels of topsoil loss during the preceding years, coupled with drought conditions, resulted in decreased agricultural productivity, leading ultimately to the Dust Bowl. To initiate a new era of soil conservation and restoration, the U.S. government implemented agricultural policies aimed at helping farmers use practices known to decrease

Soil erosion due to water runoff in a grain-producing region of Castilla-La Mancha, Spain, is attributed to a combination of management practices and high-intensity precipitation events typical of Mediterranean winters.

Source: C. Lacasta, Consejo Superior de Investigaciones Científicas, Centro de Ciencias Medioambientales (CSIC-CCMA), Madrid, Spain.

erosion and facilitate restoration of the degraded conditions. These new forms of agricultural land management, such as contour plowing and resting land, mitigated the rates of soil erosion and allowed the reestablishment of topsoil. This change led to sustainability in the form of continued agricultural fertility of the soils of the U.S. Great Plains region.

Soil desertification is another example of a soil-degradative condition. It includes several aspects of soil degradation and is generally a condition not considered to be reversible. Some regions in sub-Saharan Africa experience desertification due to population pressures on soil resources combined with climatic factors. The resulting soil degradation in the form of soil compaction and loss of nutrients is so severe, likened to the spreading of desert conditions, that restoration is not generally considered a possibility.

The processes of soil degradation depend on both human and physical variables that affect a soil region. These human and physical variables can change during timescales as short as a human life and include aspects of land management practices and decisions as well as physical environmental factors such as climate change. Improved understanding of human and physical environmental effects on the processes of soil degradation is helpful in developing ongoing management techniques and policies that specifically address current soil degradation issues characteristic of a particular region, thus improving the sustainability of soil function and resources.

The geographic variation of soil resources, environmental variables, and soil management practices results in wide spatial variability in soil degradation and degradation processes. This results in soil degradation being a location-specific condition that needs to be evaluated for a particular area in reference to a certain performance need of a soil or in reference to the alteration of the soil properties from their inherent or natural state.

Soil degradation processes are categorized as having an effect on the physical, chemical, or biological properties of a soil. The functionality of a soil depends on many interrelated processes that can also be categorized as physical, chemical, and biological. Degradation of one aspect of these general areas usually results in changes in the

other soil property areas as well. Physical degradation of soil includes erosion or loss of topsoil, soil compaction due to animal grazing or use of machinery, and breakdown of the natural soil structure. Compaction or loss of topsoil results in lowered fertility and thus less carbon cycling within the soil. Chemical soil degradation includes changes to the levels of nutrients important to sustain plant growth. Biological soil degradation is the loss of the microbial activity that is important for the breakdown of plant matter, cycling of nutrients, and soil textural properties.

SOIL DEPLETION

Soil depletion is the loss of soil fertility through a decline in organic matter content, major mineral nutrients, and trace elements. Lowered levels of nutrients lead to poor crops and deficiencies in the diet of grazing animals and, thus, eventually in the human food chain. It is a major handicap in developing sustainable agriculture. The loss of nutrients is the result of both natural and anthropogenic processes. Soils more than 200,000 yrs. (years) old on rocks poor in base elements are particularly prone to nutrient and trace element depletion. In the southeastern United States, in forest soils up to 2 million yrs. old on base-poor igneous and metamorphic rocks, calcium (Ca) in

the rooting zone has been leached out of the soil profile. This means that the potential for replenishment of soil-exchangeable Ca through mineral weathering is low. The natural nutrient cycle maintains sufficient soil fertility for tree growth, but once that cycle is disrupted, through timber harvesting, base elements are rapidly depleted. Exploitative agriculture from 1800 to 1920 in these forests depleted much of the original pre-European Ca in the soil. Mid-20th-century acid deposition (sulfate [SO₄] loading) accelerated soil Ca losses. Such effects are widespread in Europe and the United States. Soil depletion also occurs on younger postglacial soils, for example, in Maine, but less rapidly than in the southeastern United States, because the levels of acid deposition and rates of Ca accumulation in trees are lower. The conifer trees of Maine grow more slowly and require less Ca than the southeastern U.S. hardwoods.

Soil depletion is of concern to most low-latitude countries. All continental African countries, except Libya, experience annual nutrient deficits. Soils in densely populated parts of the semiarid, arid, and Sudano-Sahelian areas lose 60 to 100 kg ha⁻¹ yr⁻¹ (kilograms per hectare per year) of nitrogen, phosphorus, and potassium (NPK). These shallow, highly weathered soils are subjected to intensive cultivation but low levels of fertilizer application. In subhumid and humid African regions, rates of nutrient depletion range from 30–60 kg ha⁻¹ yr⁻¹ NPK in the humid forests and wetlands in Southern Central Africa to more than 60 kg ha⁻¹ yr⁻¹ in the East African highlands.

Globally, in 2000, soil nutrient deficits averaged (in kg ha⁻¹ yr⁻¹) 18.7 for N, 5.1 for P, and 38.8 for K, covering 59%, 85%, and 90% of harvested area in the year 2000, respectively, and annual total nutrient deficit was 5.5 Tg (teragrams, 1 Tg = 1,012 g) for N, 2.3 Tg for P, and 12.2 Tg for K, coupled with a total potential global production loss of 1,136 Tg/yr. Soil depletion is producing fertility problems throughout the world.

SOIL EROSION

Soil erosion refers to the removal of soil materials from their original location and their subsequent transport to another location through the action of wind, water, ice, biotic processes, or human activities. Under most natural conditions, soil-forming processes and soil erosion are in equilibrium. When the balance between these two forces is upset through the removal of the natural cover, soil erosion can accelerate and result in loss of the soil's capacity to support vegetation or in the soil's complete removal.

Factors Affecting Soil Erosion

Factors affecting soil erosion include climate, soil properties, slope gradient and length, vegetation, and soil management practices. Drier climates mean less vegetation and less plant cover to protect the ground surface from raindrop impact and from the flow of water over the surface. Drier soils are also more susceptible to wind erosion than moist soils due to lower particle cohesion. Soils with low clay content and a high content of fine to medium sand tend to be most susceptible to erosion from water and wind. Soils with high clay content tend to be less susceptible due to their ability to form stable aggregates that are resistant to erosive forces. Steeper slopes mean that runoff flows more

Severe soil erosion in a wheat field near Washington State University

Source: Jack Dykinga/Agricultural Research Service, U.S. Department of Agriculture.

rapidly, and with more erosive force, while longer slopes provide greater distances for runoff to build up speed. Vegetation reduces soil erosion by providing cover to protect soil surfaces against erosive forces, while organic matter from the breakdown of plant residues helps produce stable soil aggregates. Management practices that build up soil organic matter, increase groundcover, and incorporate other methods of soil conservation help lower erosion risks.

History of Soil Erosion

Since humans began growing crops and modifying the landscape, accelerated soil erosion has been a major problem facing humankind. Soil erosion has been among the culprits blamed for the decline of civilizations such as the Mesopotamian civilization, the Classical Mayan civilization, and the Roman Empire. Soil erosion is also linked to the mass exodus of migrants in the 1930s from the western Great Plains when drying conditions combined with severe wind erosion set off the series of events that turned the region into a “Dust Bowl.”

Humans have long been aware of the consequences of accelerated soil erosion caused by their activities. Passages in the Old Testament mention threats of streams drying up, while the Greek philosopher Plato referred to the relationship between flood damage and deforestation, and the Roman writer Virgil advocated what amounted to conservation farming. Many early civilizations were not overly concerned with erosion’s impacts because most of these civilizations had developed on irrigated alluvial plains, and thus, they counted on erosion in the headwaters of rivers such as the Nile, the Tigris, and the Euphrates to provide sediments to renew soil fertility.

By the late 18th century, however, more observers began to notice the consequences of accelerated erosion, partly due to the increased impacts of humans on the landscape as populations began to grow at unprecedented rates. In 1818, James Madison lectured on the evils of poor land management. In 1864, George Perkins Marsh wrote about the impacts of forest clearance on river sedimentation and flooding in New England and the Mediterranean Basin.

German soil scientists conducted the first scientific investigations of soil erosion in the 1870s. The U.S. Forest Service first conducted quantitative soil erosion experiments in 1915 in Utah. In 1928, Hugh Bennett of the Soil Conservation Service established a network of field experiment stations that enabled work on the analytical study of the erosion process. In 1954, a national study of soil erosion used modern data analysis techniques to correlate the results of all field experiments to identify and mathematically enumerate the main factors in the erosion process. This allowed for the development of equations that could be used to estimate the soil erosion in an area based on a number of known variables such as rainfall amount and intensity, slope gradient, slope length, soil erosivity, vegetation cover, and the soil management system.

Geographic Extent of Soil Erosion

There are many difficulties involved in estimating soil erosion impacts on a large scale due to the huge variations in soil type, rainfall, management practices, slope, and vegetation that occur over large areas. The use of different assumptions and methods of measurement and analysis also leads to wide variations in erosion estimates. Also, while industrialized countries such as the United States and the United Kingdom have well-funded agencies that produce annual reports on the impacts of soil erosion on croplands under their jurisdiction, similar data are harder to come by in poor countries such as Ethiopia or Guatemala.

In 2003, total annual erosion on all cropland in the United States was estimated at 1.75 billion tons, with 970.6 million tons removed by water and another 776.4 million tons removed by wind. This converts to average per-acre soil losses of 2.6 tons due to water-induced erosion and 2.1 tons due to wind-induced erosion. Although the overall soil loss figures were lower than the overall estimated soil loss rates for 1982, 102 million acres (28% of all cropland) were still losing soil at rates above the soil loss tolerance limits.

One study of the mean water-induced global soil erosion rates between 1979 and 1993 estimated the total annual erosion losses for that period to be around 4.7 tons acre⁻¹ yr.⁻¹ (per acre per year), with the highest overall soil losses

estimated for South America (6.8 tons acre⁻¹ yr.⁻¹) and Asia (6.4 tons acre⁻¹ yr.⁻¹). However, erosion losses in mountainous regions can be as much as 100 tons acre⁻¹ yr.⁻¹ or more.

SOILS

A soil is a body of weathered mineral and organic materials that has been altered through time into a series of discrete layers. The movement of water through the materials facilitates the development of layers (horizons) that are distinguished by whether they have lost or accumulated different mineral and organic constituents (Figure 1). A number of strongly interrelated variables contribute to the development of a soil; these are most succinctly summarized by Hans Jenny's *clorpt* equation, which emphasizes the interaction of the five soil-forming factors of climate, organisms, relief, parent material, and time.

Every soil starts from an accumulation of some type of parent material (fractured bedrock, river alluvium, glacial till, wind-blown loess, plant residue, etc.) that is then altered through time by weathering processes that are highly dependent

Figure 1 Soil profile illustrating the typical sequence of horizons. O horizons are dominated by decomposing organic material; A horizons are mineral horizons enriched with organic matter; B horizons are most often illuvial horizons, with the illuviated material largely dependent on the interaction of the soil parent material, climate, and time; C horizons represent relatively unaltered parent material. If present, unaltered parent material would be represented by an R horizon.

Source: F. D. Wilkerson.

on the climate (long-term patterns of precipitation and temperature). The organisms (plants and animals of all sizes, including microbes) involved in soil formation are also closely linked with the climate. The landscape position (relief) affects the potential energy for movement of materials into and out of the original parent material. Additions to the parent material can include mineral particles (e.g., dust) and organic materials from decaying plants and animals. These additions and the original parent material are altered by physical and chemical weathering, and through time, the various weathered products are moved (translocated) throughout the parent material, forming what is referred to as a *soil profile*.

Regardless of the dominating soil-forming factor, the presence of water is critical to the formation of a soil profile and its characteristic horizons (layers). A desert soil exhibits very different attributes from a soil developed in a humid environment, but water is a crucial component in both. On the planet Mars, even without what we recognize as plants, the presence of water supports the existence of Martian soils. Water-related soil processes point to its significance in chemical reactions within the soil and its role as a medium for the movement of different materials in solution (leaching) or in suspension. The movement of water is driven by gravity, so the majority of translocation within a soil profile proceeds from the top of the profile downward through time. This movement is facilitated by the presence of soil pores (voids or air spaces), which occur within the profile in a variety of shapes, sizes, and connectivities. As translocations proceed over time, soil components are removed from certain horizons and concentrated in others. Horizons that have lost a certain component are called *eluvial horizons* (soil components have exited that horizon), while horizons with an accumulation of translocated components are *illuvial horizons* (soil components have moved into the horizon).

Weathered parent material contains a variety of minerals characteristic of the chemical composition of the original material. Salts are a common weathering by-product and are the first components to be translocated in solution through the soil profile. In humid environments with adequate water, the majority of salts are easily leached from the soil profile. Tropical soils developed under conditions of plentiful water and warm temperatures are heavily weathered and leached and thus retain little evidence of the original parent material chemistry. When the majority of soluble materials have been removed from tropical profiles, the soils are highly acidic, and they are dominated by iron and aluminum oxides.

In arid environments, salts are not completely leached away but are precipitated from solution within the soil profile, and the climate is actually recorded in the type and amount of salts present and the depth of salt precipitation. The depth of salt deposition within a soil profile marks the maximum depth of water movement, which is the depth at which the salts are chemically

precipitated as they are forced out of the solution. Sodium salts are the most soluble, followed by potassium and calcium. In extreme cases, a soil profile will have deposits of sodium salts at or near the surface of the profile, which results in a physical and chemical environment that is inhospitable to plant growth. As water amounts increase, the sodium and potassium salts will be flushed from the soil profile, and calcium will begin its translocation through the soil. Calcic horizons (soil layers with an accumulation of CaCO_3 [calcium carbonate]) are characteristic of semiarid and arid soils, where the depth-to-carbonate is indicative of the mean annual precipitation.

Once the soluble salts (e.g., sodium, potassium, and calcium) have been leached out of a soil horizon, other soil constituents can begin their translocation process. The movement of clay minerals is one of the more important soil formation processes. Clay minerals are very small particles (<0.002 mm [millimeters]) that have a wide range of chemical composition and either can weather directly out of the parent material or can be secondary minerals formed within the soil profile. Regardless of their source, clay mineral particles are translocated throughout the soil profile by moving water. Soil layers with an accumulation of clay particles tend to take on a reddish color and are known as *argillic horizons*. The presence of high amounts of clay within a horizon can affect both physical and chemical properties of a soil profile.

The mineral-based particles within a soil are referred to as *soil separates* and are categorized by size. Sand-sized particles are 0.05 to 2.0 mm in size and are usually dominated by a resistant quartz (SiO_2) mineralogy. Silt-sized particles range from 0.002 to 0.05 mm and are often described as exhibiting characteristics similar to flour. Clay-sized soil separates are particles <0.002 mm in size and are dominated by plate-like clay mineral particles. The relative proportion of soil separates (expressed as a percentage) defines its texture. Soil textural classes are given descriptive names that define a specific range of soil separates: Loam (7%–27% clay, 28%–50% silt, $<52\%$ sand), silty clay loam (27%–40% clay, $<20\%$ sand), and sandy clay loam (20%–35% clay, $<28\%$ silt, $>45\%$ sand) are a few examples.

There are a total of 12 textural classes defined, and they are most commonly graphically represented on a soil textural triangle (Figure 2).

Soil texture can vary from horizon to horizon and is controlled by the texture of the original parent material in conjunction with the physical and chemical weathering processes occurring within the soil profile. The translocation of clay minerals is a dominant soil formation process and is usually responsible for the abrupt changes in texture within a soil profile. Additions of wind-blown fines (usually silt-sized particles) can enhance the texture of surface horizons, while parent material textures tend to dominate the lower horizons. A granitic parent material will weather into sand-sized particles, shales into clays, limestones into silts, and sandstones into sands. Mixed parent materials such as glacial tills support highly variable soil textures but are usually dominated by the finer components (silts and clays) of the till matrix.

The soil textural class provides clues to a variety of physical and chemical properties. The ability to hold water and plant nutrients is controlled to a large extent by the particle size. Sand grains are large and do not pack closely together, so sandy soils have large pores but a relatively small amount of open pore space compared with the mineral grains. A soil high in sand will tend to be porous and, thus, well drained, with a relatively low water-holding capacity. The very small, plate-like clay particles pack closely together, resulting in small pores but overall a large amount of space between the clay particles. A soil high in clay will tend to be dense and poorly drained but with a high water-holding capacity. High-clay soils can hold two to four times more water than a sandy soil. The surface area of the mineral particles controls their ability to hold nutrients for plant uptake. Sand grains have a relatively small surface area, while the very small clay particles have a high proportion of surface area available for plant nutrient adsorption. Sandy soils are relatively infertile, while high-clay soils have a much greater capacity for storing plant nutrients. Many soil-engineering properties are defined by soil texture and related textural characteristics such as plasticity.

The presence of clays, organic matter, and microbes within a soil profile help to aggregate

Figure 2 The soil textural triangle provides a graphic representation of the percentage of soil separates in each textural class.

Source: Courtesy of U.S. Department of Agriculture, Natural Resources Conservation Service.

(glue) soil separates into coherent units called *peds* (from the ancient Greek *pedo*, meaning “ground” or “earth”). The soil peds are collectively referred to as the *soil structure*, and like texture, the structure can vary from horizon to horizon within a soil profile. Soil structure is defined by the size, shape, and strength of the aggregated peds, with shape being the most

descriptive characteristic. Ped shapes include granular, blocky, platy, prismatic, and massive. Soil structure plays a role in controlling several physical properties within a soil profile, including drainage, water-holding capacity, aeration, and the environment for root penetration and growth. A massive soil structure acts as a dense, homogeneous unit with restricted pore space and thus

restricted aeration, water movement, and water-holding capacity as well as restricted root access. A massive structure is in direct contrast to a granular structure, which is dominated by an accumulation of small, rounded aggregates that allow for ample aeration, water movement, and storage and an ideal root growth environment.

Like the physical soil properties of texture and structure, soil chemistry is closely tied to the soil parent material and the weathering processes that occur within the profile. Soil chemistry is complex and includes a wide range of chemical reactions across incredibly varied environments. Most chemical weathering reactions that can be replicated in a laboratory occur naturally in soils, including oxidation, reduction, carbonation, dissolution, hydration, hydrolysis, and solution. Soil chemistry is most significant for its role in determining soil fertility and the availability of nutrients for plant growth, but it also plays an important role in controlling certain physical properties. Soil pH and cation exchange capacity (CEC) are two of the more important soil chemistry attributes.

In drier climates, the soil pH is closely tied to that of the original parent material, while in humid climates, chemical weathering processes dominate the profile. Limestone (CaCO_3) has a normal pH of 8, and the resulting soils will maintain that basic pH in drier climates, while granitic soils will be acidic due to the chemistry of the original granite. The accumulation of salts in arid environments also helps support basic pH levels (salts will accumulate when evaporation exceeds the water available for leaching). Humid subtropical to tropical climates are dominated by leaching, and chemical reactions lead to acidic soils with no recognizable chemical ties to the original parent materials.

Soil pH is linked to the availability of nutrients to plants. A neutral pH (pH 7) is preferred by many plants, as pH levels to either extreme (acidic or basic) mean that many nutrients are either not available for plant uptake or are present in high enough levels to be toxic. Some plant communities have naturally adapted to extreme pH levels. Cranberries (*Vaccinium macrocarpon*) prefer acidic soil pH levels between 4.5 and 5.5, and *Rhododendron* spp. prefer a pH level of 5.5. The longest-lived species on Earth, *Pinus longaeva* (bristlecone pine), prefers dolomite ($\text{Ca}\cdot\text{Mg}(\text{CO}_3)_2$)

substrates with a basic pH because the dolomitic soils at this pH level are nutrient-deficient for most plants and the bristlecone are able to out-compete their associated species. Commercial agriculture and horticulture applications often add chemical amendments to adjust the soil pH to the optimum level for the plant species under cultivation.

Soil is often defined as the medium that supports plant growth, but it should be remembered that plants can also grow out of the cracks in bedrock and flourish hydroponically in water. Plants and soils are unquestionably interconnected, as soils supply a physical medium for plant root growth and nutrition and plants supply essential organic material for soil formation, including through recycling of plant nutrients. The interaction between climate, vegetation type, and soil formation is also significant and self-perpetuating.

CEC is the main measurement used to quantify soil fertility. As a whole, a soil will have a neutral charge, with exchange sites on mineral particles and with positive and negative ions in solution. Common ions in the soil solution are the positively charged ions (cations) of calcium (Ca^{+2}), magnesium (Mg^{+2}), potassium (K^{+}), ammonium (NH_4^{+}), sodium (Na^{+}), aluminum (Al^{+3}), and hydrogen (H^{+}). Calcium, magnesium, potassium, and nitrogen are all important plant macronutrients; while sodium is an important plant nutrient, it can be detrimental to a plant's osmotic potential if present in too large quantities (typical of some coastal and arid environments or irrigated settings with inadequate drainage or flushing). Aluminum is toxic to most plants when it is the dominant cation at very low pH levels (exchangeable Al^{+3} ions dominate at levels below pH 4). There are also negatively charged ions (anions) in the soil solution that serve as plant nutrients, including chloride (Cl^{-}), nitrate (NO_3^{-}), sulfate (SO_4^{-2}), and phosphate (PO_4^{-3}).

Organic matter and clay mineral particles are the dominant source of exchange sites within a soil, and both are negatively charged particles with a majority of their exchange sites available for cation exchange (negative sites for holding and exchanging positively charged cations). Both organic matter and clay minerals are relatively small particles with a large proportion of surface area, so a high number of exchange sites are available. Other soil particles, such as sand, have a

relatively small surface area; they are essentially chemically inert (dominated by quartz SiO_2) and offer few if any exchange sites. Plant roots can access the ions held on exchange sites, and while free ions in solution are the most readily available, they are also the most readily leached out of the root zone.

CEC is measured in milli-equivalents (or meq) of negative charge per 100 g (grams) of soil. The CEC of pure clay minerals will vary with their chemical structure, but most are in the upper end of the 5- to 150-meq/100 g range. Soil organic matter CEC is the highest, with an average of 200 meq/100 g. Given the exchange capacity of clays compared with sands, the texture of a soil can be used to estimate CEC. The following textural classes illustrate the role of soil texture in CEC: sandy loam, 2 to 4 meq; loam, 2 to 17 meq; silt loam, 9 to 26 meq; and clay, 5 to 58 meq. Regardless of soil texture, the presence of organic matter has a strong influence on soil CEC, given that the exchange capacity of organic matter is 4 to 50 times larger than that of clay minerals.

Soil organisms are also important for soil fertility through their role in breaking down plant and animal remains into their elemental constituents. Burrowing organisms of all sizes (from badgers, rabbits, gophers, etc., to earthworms and burrowing insects) are important for their role in incorporating organic material into the mineral horizons where the microorganisms (mainly bacteria, but also fungi) can begin the decay process. The organic matter produced from the decomposition of plant and animal remains improves not only a soil's CEC but also its physical properties by increasing its aeration and water-holding capacity. Organic matter is also a key component in improving soil structure.

One of the most significant soil organism processes is the nitrogen cycle. Nitrogen is a major plant macronutrient, and 90% of Earth's nitrogen occurs as a stable gas (N_2) in the atmosphere. The majority of soil nitrogen comes from soil bacteria fixation of the atmospheric N_2 into the inorganic ammonium form (NH_4^+). Other soil bacteria will mineralize lesser amounts of NH_4^+ from decomposing plant and animal remains. Nitrifying bacteria will convert much of the NH_4^+ to the more plant-preferred, but also more readily leached, forms of nitrite (NO_2^-) and nitrate (NO_3^-). And to

complete the nitrogen cycle, other microscopic species will denitrify some of the soil NO_3^- and actually send nitrogen back into the atmosphere.

Larger mammals also play a role in the soil-forming process. Many of the larger wild animals disturb the soil surface through a variety of behaviors, including grazing, hoof impact, digging, and wallowing. Although these behaviors are disruptive to the vegetation and surface horizons, they are also important in establishing seed contact and in some cases even increasing aeration and surface water infiltration. Domestic animals (especially grazers) have some of the same habits, but often their behaviors are artificially restricted, so that instead of increasing seed contact and aeration, the soil becomes compacted, and soil structure is negatively affected.

Humans are by far the most influential organism in the soil formation equation. Most impacts from human interaction with the soil are negative. Soil erosion is a natural process, but it has been greatly increased through disturbance by people cultivating, logging, and clearing vegetation for urbanization. We are able to feed large populations through the use of domesticated plants and commercial agriculture, but at a price to soil formation. Decomposing plant remains are a good source of soil organic matter and nutrients, but harvesting of food and animal feed crops removes the majority of plant material before it even gets into the soil cycle. Inorganic chemical amendments (fertilizers, herbicides, pesticides) used to increase crop yields can have negative impacts on soil organisms and physical characteristics such as soil structure. Global movements toward more organic and sustainable methods of agriculture have the potential to reduce, and in some cases even reverse, the negative impacts of humans on soils.

Many different international soil classification (taxonomy) systems exist to help categorize soils into different groups. Most of these are systems developed to fit the needs of specific countries, with more specialized classifications being used by construction engineers and for other technical applications. Countries with well-established agricultural sectors have the most well-known soil taxonomies, including Russia, Canada, the United States, Israel, and Australia. The basis for each taxonomy system varies, but a familiarity with one system usually makes it easier to understand

Typical Mollisol profile. Mollisols (one of 12 soil orders in the U.S. soil taxonomy system) are common under midlatitude grasslands and are defined by their organic-rich A horizons. The whitish areas in the near-surface calcic horizon (Bk) are illuviated deposits of calcium carbonate that are common in these semiarid grassland soils.

Source: Courtesy of U.S. Department of Agriculture, Natural Resources Conservation Service.

Typical Spodosol profile. Spodosols (one of 12 soil orders in the U.S. soil taxonomy system) are most common under coniferous forests on sandy parent materials at latitudes over 40° N/S (cool and relatively wet climates). The horizon is indicative of eluviated horizons dominated by quartz, where the eluviated iron and aluminum compounds have accumulated in the darker horizon underlying the E horizon.

Source: Courtesy of U.S. Department of Agriculture; Natural Resources Conservation Service.

Typical Oxisol profile. Oxisols (one of 12 soil orders in the U.S. soil taxonomy system) are highly weathered tropical and subtropical soils, usually dominated by iron and aluminum oxides. The reddish color is characteristic of intensely weathered mineral soils.

Source: Courtesy of U.S. Department of Agriculture, Natural Resources Conservation Service.

other systems. There are two main international taxonomies developed to help facilitate global soil understanding, the soil classification system of the FAO/UNESCO (Food and Agriculture Organization/United Nations Educational, Scientific and Cultural Organization) and that of the WRB (World Reference Base for Soil Resources).

The current U.S. soil taxonomy system (developed by the U.S. Department of Agriculture's Natural Resources Conservation Service) is a hierarchical classification system based on the presence (or absence) of specific diagnostic horizons. At the most detailed level of classification, there are hundreds of soil series identifiable within the United States, and all can be fit into 12 general soil orders (see photos).

SOJA, EDWARD (1941–)

One of human geography's most passionate and articulate advocates, Edward Soja has long been an aggressive voice for the inclusion of space in contemporary social thought. He is widely regarded as one of the leading theoreticians in urban and political geography. His work has long been characterized by an abiding concern for issues of social justice and inequality as well as for deciphering the ways in which spatial relations are naturalized as well as contested.

From his origins in the Bronx, Soja developed a highly urban-centered geographical imagination. Following a PhD at Syracuse University, he taught briefly at Northwestern University in Chicago, where he briefly pursued a positivist line of thought. His early work concerned Africa, including a dissertation on Kenya and applications of modernization theory. However, soon after, Soja joined the faculty of Urban and Regional Planning at the University of California, Los Angeles, where he has remained since 1972.

Deeply affected by the events of the 1960s, Soja became a committed Marxist and was a major force in encouraging the discipline to see space as a social construction, that is, as made rather than simply given. Soja's works convinced many readers that space was filled with politics and meaning, that its production and reproduction lay at the core of capitalism's survival and expansion, and that spatial transformation was every bit as significant as social transformation. His early work sought out a simultaneous transformation: the "Marxification" of geography and the spatialization of Marxism. In this light, society and space were inseparable, forming a seamless "socio-spatial dialect." He was profoundly influenced by the flowering of spatial thought unleashed in France by Henri Lefebvre and Michel Foucault, playing a major role in introducing their ideas to geographers, and was one of the architects of the "spatial turn."

At the core of Soja's intellectual project lay cities in all their glorious, messy complexity. For Soja, urban life—its everyday rhythms, the division of labor, public policy, struggles over places, and the relations among distant locales—could only be comprehended meaningfully through the

conceptual lens of spatiality. In this regard, he became a firm opponent of historicism, which privileged time over space, arguing that the two dimensions necessarily held equal ontological status. But Soja was also something of an urban *flâneur*, a storyteller seeking to capture the richness of space. Soja's insistence in this regard led him into postmodernism and away from orthodox Marxism's relegation of spatiality to the periphery: A postmodern geography was one that by definition put space on a par with time. In this regard, he faced vociferous objections that he had lapsed into a form of spatial determinism.

His book *Postmodern Geographies*, published in 1989, drew enormous favorable attention worldwide and established him as one of the discipline's leading theoreticians. Rather than simple dichotomies, such as those that pervaded most Enlightenment thought, Soja advocated a "trialectics" consisting of time, space, and meaning. In this reading, the production of spatiality was always open-ended and contingent, never preordained. Empirically, the heart of Soja's agenda lay in Los Angeles, the globalized, post-Fordist, enormously diverse metropolis in which social inequalities are inevitably matched by equally appalling spatial inequalities. He was thus a founding member of the "Los Angeles School" of urban studies, which took as its point of departure that city's experiences in the late 20th century.

In *Postmetropolis*, published in 2000, Soja extended his urban emphasis into a geohistory of spatiality, drawing, for example, on the examples of Jericho and Catal Hüyük to offer a "provocative inversion" that puts early urbanization at the core of the process of domestication. This argument relies heavily on his notion of "synekism," essentially the agglomeration economies and higher rates of creativity induced by face-to-face contact in dense urban environments, including the informal linkages, unstandardized knowledge, and intimate interconnections that are essential for the generation of new ideas, practices, and technologies.

per year]) at the highest latitudes to a high of 0.25 kW/m^2 ($\sim 2,200 \text{ kWh m}^{-2}/\text{yr.}^{-1}$) in some desert areas of Africa and Australia. Conversion of this potential energy into secondary forms, such as electricity or process heat, depends on technical factors (e.g., efficiency of converters such as photovoltaic cells or thermal collectors), economic constraints (e.g., the absolute and relative costs of technology and fuels), and suitability considerations (e.g., the suitability of land or ocean use for locating the collection infrastructure). Nonetheless, the abundance of solar energy surpasses all other sources of renewable energy. Estimates of the technical potential of solar energy versus wind, biomass, geothermal, and ocean sources of energy show that solar energy represents our largest source of renewable energy supply and a key technology to lower worldwide carbon emissions.

There are several solar energy technologies, which can be arranged along the following continuum: (1) passive and active, (2) thermal and photovoltaic (PV), and (3) concentrating and nonconcentrating. *Passive solar* energy technology collects the energy without converting the heat or light into other forms. In contrast, *active solar energy* technology refers to the harnessing of solar energy to store it or convert it for other applications and can be broadly classified into two groups, namely, PV and solar thermal. Solar PV cells are the “high-tech” option among active solar energy strategies, directly converting solar energy to electricity. Solar thermal applications include two distinct technological streams. The first stream, referred to as *solar thermal nonelectric*, includes applications such as agricultural drying, solar water heaters, solar air heaters, solar cooling systems, and solar cookers. The second stream of solar thermal technology, referred to as *solar thermal electric*, includes technologies that use the sun’s heat to produce steam and generate electricity. The final characteristic in the continuum of solar energy technologies is *concentrating versus nonconcentrating* technologies. Concentrating solar power (CSP) technologies use mirrors or lenses (concentrators) to focus sunlight and thus increase the intensity of light in the focus area. In addition to CSP, concentrators can be applied in PV technologies as well by using a dish collector or optical lenses to concentrate sunlight on a smaller cell area.

SOLAR ENERGY

Solar energy is the most abundant renewable energy source on the planet. The energy influx from solar radiation striking land surfaces is sufficient to meet the present primary commercial energy needs of the world thousands of times over. Usable solar influx is affected by diurnal and geographic variation and weather. Worldwide, the yearly average values of effective solar irradiance reaching Earth’s land surface vary from a low of 0.06 kW/m^2 (kilowatt per square meter; $\sim 500 \text{ kWh m}^{-2} \text{ yr.}^{-1}$ [kilowatt hours per square meter

The solar hot water system at the Adams County Detention Facility, northeast of Denver, Colorado, has been operating since 1988; it exemplifies the benefits users can reap from solar heat. This parabolic trough-based system supplies 46 % of the hot water used in the jail's kitchen, laundry, and showers, which is about 20,000 gallons per day.

Source: Warren Gretz.

In addition to technological differences, solar technologies can be characterized according to their applications. There are broadly three types of solar applications: (1) centralized utility-scale installations, (2) grid-connected distributed installations, and (3) off-grid installations. Centralized utility installations are typically large-scale PV or CSP systems, operating like other conventional power-producing plants, dispatching electricity over thousands of miles to customers. Distributed grid-connected and off-grid applications, in contrast, are smaller in scale and are located on-site, where the energy will be used. These applications can be electric (e.g., PV) as well as nonelectric (e.g., solar hot water). In recent years, distributed solar applications have experienced rapid growth, representing the fastest-growing new energy generation source in the world, with an astonishing

50% global market growth rate in 2007. Its use is primarily concentrated in the industrialized countries, where policy incentives introduced in recent years have spurred its adoption (e.g., “feed in” laws, renewable portfolio standards, tax incentives, rebates, and net metering). The use of urban rooftops to host the technology makes solar systems adaptive to human settlement patterns. Water-heating solar systems are frequently competitive with conventional energy alternatives. Globally, this technology is being rapidly adopted in both industrialized (Germany, the United States, Japan, Israel) and developing countries (China, India, Brazil, Turkey, and South Africa). China currently has more than half of the existing solar hot water and heating applications in the world. Its Renewable Energy Law encourages installation and use of solar thermal systems, and

parts of China already are moving toward solar water heating obligations.

Production of solar technologies is now part of the global economy, with manufacturing and assembly spread over all human-inhabited regions. In contrast, installation of the technology largely draws from the local labor force. The size of the industry is slated to grow rapidly as improvements in cell efficiency occur (analysts project a doubling of efficiency to 24% or more in 5–8 yrs.) and as costs of production continue to fall (grid parity without subsidies is expected to be reached between 2012 and 2015). When these milestones are reached, solar technology will likely become the most important means of energy production for carbon-constrained societies.

SOLSTICES

Solstices are points along the path of the sun's apparent orbit (also known as the *ecliptic*) that, when viewed from a point on Earth, mark where the sun is at its farthest from the extension of Earth's equator across the night sky, also known as the celestial equator. The term *solstice* literally means "sun stoppage" due to the apparently long day.

During the summer solstice, in the Northern Hemisphere, the sun appears at its farthest point above the celestial equator; that is, it is at its "highest" in the sky. The exact time of this astronomical phenomenon varies, as the calendar year does not perfectly match the solar year. Hence, although the summer solstice usually falls on June 21 or 22, the specific date does not always correspond to the longest day of the year (for those residing in the Northern Hemisphere). With each year, the solstice drifts 6 hrs. (hours; a fourth of a day, since the solar year is actually 365.25 days long). For those residing in the Southern Hemisphere, the same constraint also applies, although there is the additional confusion that during the Northern summer solstice, the sun is farthest below the celestial equator, and it is thus the Southern winter solstice at this time, during which they have their shortest day, or alternatively, the longest night, of

Stonehenge attracts some 800,000 visitors a year, and on the summer solstice, thousands of people gather to watch the sunrise.

Source: Morguefile.

the year. The exact opposite scenario occurs on December 21 or 22, with the Northern Hemisphere experiencing its longest period of night and the Southern Hemisphere experiencing its longest period of daylight. The effect is amplified with increasing degrees of latitude, with the equator experiencing the least amount of variation in daylight and the poles the greatest during the respective solstices. Within the equatorial astronomical coordinate system, the summer solstice in the Northern Hemisphere corresponds with a right ascension of 6 hrs. and a declination of 23.5° , which places the sun within the Tropic of Cancer during this period. During the winter solstice, the sun is within the Tropic of Capricorn, with a declination of -23.5° and a right ascension of 18 hrs.

In many European cultures of antiquity, the summer solstice was regarded as midsummer and celebrated with festivals. Contemporary Europe still maintains some aspects of midsummer festivals, notably in Ireland and Scandinavia. The primary motive for these celebrations derives from the solstice's relation to the onset of the fall harvest, since it has long been observed as the point

at which day length maximizes and then begins to wane into autumn. (However, in American popular culture, it is commonly regarded as the "beginning of summer.") The solstice is celebrated with festivals by Christian communities throughout the world as "St. John's Day" if celebrated on June 24 or "St. John's Eve" if celebrated the night before; however, neither is this day technically the longest day of the year, nor can it be traced historically to any aspect of the life of John the Baptist. The specific commemoration of John refers to the close association of the opposite solstice, on December 21 or 22, with Christmas, which has been refigured as the birthday of Jesus. The theologically inspired argument is that John the Baptist heralds the coming of Jesus Christ, hence his holiday should come before. In this respect, though the winter solstice is commonly regarded as "the beginning of winter" in most Christian-majority countries (though astronomically, it signals the beginning of increasing amounts of daylight), it is overshadowed by the Christmas holidays that occur several days later. The close association is not coincidental, as early Church officials

deliberately sought ways to incorporate pagan holidays into the Christian belief system.

The solstices' relation to pre-Christian religious traditions in Europe has also been invoked in interpretations of megalithic structures throughout the British Isles, notably at Newgrange in Ireland and Stonehenge in Britain. In both instances, the argument is that the stones were specifically aligned to predict or signal the specific day on which the solstice would occur. In the case of Newgrange, the apparent effect of a beam of sunlight entering the main chamber passage from above and slowly tracing a path along the chamber floor was taken by some as evidence that it was deliberately designed for such an effect. However, since the ruins had to be rebuilt after excavation, it is difficult to establish whether the initial designers had this effect in mind or whether it is simply an unlikely coincidence. In the case of Stonehenge, the argument has been made that on the summer solstice the sun appears to rise just above a specific stone, while on the winter solstice, the moon appears to rise above the same stone. In this case, since the structure is arranged in a circle, it is difficult to rule out that the effect is simply a matter of probability, although it is theoretically possible. Most scholars agree that the stronger case can be made for Newgrange having been originally designed for this effect, since it would have been difficult for the modern reconstruction to deliberately incorporate such a feature, given the short amount of time allotted for reconstruction.

Solstices are also celebrated in non-European cultures. In Chinese culture, the winter solstice is celebrated as "Dong Zhi," which literally means "the arrival of winter." Dong Zhi is celebrated essentially in the same manner as Christmas and Thanksgiving in the Christian world, as a time for families to gather for large feasts. A traditional dish served on Dong Zhi consists of often brightly colored rice dumplings filled with lamb and other ingredients. Furthermore, similarly to pagan European interpretations, Dong Zhi is acknowledged as a midpoint in winter—marking the beginning of more daylight rather than the onset of winter. Within Chinese traditional cosmology, the winter solstice is believed to symbolize the peak of Yin energy (dark, cool, feminine) and the beginning of Yang ascendance (fiery, masculine energy).

SOVEREIGNTY

As a general term, *sovereignty* can be defined as the absolute authority of a state within its territory. As a theoretical construct, "sovereignty" can be deconstructed into two major components: (1) a state's self-perceived, inalienable right to universal authority, particularly the use of force within its boundaries, and (2) the recognition of such authority and boundaries by the international community. Because sovereignty encompasses the most basic quality of a state—the right to exist—concepts of and conflicts over sovereignty have fundamental implications for international law. Sovereignty is also intrinsically geographic by the nature of its definition; it is contingent on geography not only for determining the literal extent of state power but also for providing the geopolitical context in which states exercise their sovereignty.

However, sovereignty can neither be analyzed nor defined in a contextual vacuum. In 1918, U.S. Supreme Court Justice Oliver Wendell Holmes stated, "A word is not a crystal, transparent and unchanged. It is the skin of a living thought and may vary greatly in color and content according to the circumstances and the time in which it is used" (cited in Reisman, 1990, p. 872). When Holmes's axiom is applied to *sovereignty*, we end up with a theoretical construct that is highly dynamic and context-reflective. In essence, the means by which states claim, enforce, and defend their sovereignty have changed throughout

time, reflecting the geopolitical status quos of different eras.

Etymologically, *sovereignty* is derived from the term *sovereign*, which in turn originates from the absolute monarchies of feudal Europe. In these monarchies, the power of the state, particularly legitimacy over the use of force, was contained within a single person, who often claimed authority through divine providence. While documents such as Magna Carta (1215) limited the power of the absolute monarch in the latter half of the Middle Ages, sovereignty was still limited to a “geography of one.”

Sovereignty arose as a legal/geopolitical phenomenon resulting from the 1648 Peace of Westphalia. The concluding document to the Thirty Years’ War (1618–1648), the Peace of Westphalia (recognized as the first “modern” international treaty), among other territorial compromises, allowed the individual states comprising the Holy Roman Empire to choose their own religion, a power that had been usurped by the Holy Roman Emperor. At the time of the Thirty Years’ War, religious institutions played a significant role in executing state functions, as well as being the largest authoritative presence in the daily lives of the people. Thus, by granting the state sole authority for religious determination, the Peace of Westphalia established the legal precedent for the aforementioned first component of sovereignty: State governments have absolute authority over affairs within their prescribed territories, to the explicit exclusion of external actors. Geography is the crucial contextualizing agent in what scholars have come to call “Westphalian sovereignty.” The concept of Westphalian sovereignty has been the foundation of the international system for more than 360 years.

The ability of a state to have absolute and sole control over its domestic affairs would be functionally nullified without the second component of sovereignty: international recognition. Signatories to the Peace of Westphalia as well as the subsequent international system that embraces Westphalian sovereignty, by electing to operate within that system, implicitly accept the second component. Demanding sovereignty over one’s own territory necessitates recognizing separate geographies of influence under the control of neighboring states/sovereigns.

The functional results of the application of Westphalian sovereignty, embodied in the execution of the Peace of Westphalia via the recognition of other states’ sovereignty, are reflective of the interconnectivity between sovereignty and international law. The International Court of Justice (ICJ), the current de facto governing institution of international law, delineates official sources of international law as “1) international conventions, whether general or particular, establishing rules expressly recognized by the contesting states; 2) international customs as evidence of general practice accepted by law; 3) the principles of law recognized by civilized nations” (United Nations, 1945). As evidenced by the first section of the ICJ’s definition of international law, the principles of sovereignty embodied by the Peace of Westphalia, and the contemporary international system that embraced those principles, are reflective of the “nexus of interaction” that joins sovereignty and international law at the hip.

During the Cold War, concepts of sovereignty were contextualized by the greater geopolitical struggle between East and West. The establishment of NORAD (North American Aerospace Defense Command) is one such example. By allowing the United States to centralize the defense of the North American continent, Canada’s air defense was essentially taken out of the hands of the Canadian government. Thus, the Canadian state’s control over events in its internationally recognized territory was usurped in the name of a greater geopolitical “good,” in violation of the concepts of strict Westphalian sovereignty.

Sovereignty in the 21st century will once again be defined by its geopolitical context. As climate change progresses via anthropogenically augmented global warming, the system of international legal institutions and treaties on which an increasingly globalized humanity relies is being stressed to the breaking point. Treaties such as the United Nations Law of the Sea, which delineates and arbitrates sovereignty over maritime resources, rely on static geographies (e.g., coastlines and permanent ice sheets) to assign sovereignty over increasingly scarce natural resources. When combined with increased access to these resources via the loss of polar ice caps, population pressures on natural resources, and a rise in

“antiglobalization” nationalism, the ambiguous sovereignty created by dynamic geographies creates a geopolitical environment that promotes state-versus-state conflict.

Despite the relative perpetuity of Westphalian sovereignty’s influence on the structure of the modern international system, the theoretical construct of sovereignty remains a hostage to the geopolitical context in which it is applied. In addition, the interconnectivity between the structure and status of the international system of jurisprudence (functional/nonfunctional, the existence of a hegemonic state, etc.) affects how states choose both to enforce their own sovereignty and to respect the sovereignty of other states. More than any other factor, it is the geopolitical context, specifically competition between state actors within the international system, that has defined the role of the concept of sovereignty for three and a half centuries.

SPACE, PRODUCTION OF

See Production of Space

SPACE OF FLOWS

The *space of flows* is a term coined by the sociologist and urban planner Manuel Castells to describe the geographies of the globalized postindustrial informational societies that emerged in the late 20th century, in which productivity is derived primarily from knowledge and information. Concomitant with this transformation, social scientists have searched for new frames of reference to make sense of the emerging geographies of centrality and peripherality unleashed by flexible globalization.

In Castells’s (1996) reading, the time-space compression of postmodern capitalism was manifested in the three “layers” of transportation and communication infrastructure, the cities or nodes that occupy strategic locations within these, and the social spaces occupied by the global managerial class:

Our societies are constructed around flows: flows of capital, flows of information, flows of technology, flows of organizational interactions, flows of images, sounds and symbols. Flows are not just one element of social organization: they are the expression of the processes dominating our economic, political, and symbolic life. . . . Thus, I propose the idea that there is a new spatial form characteristic of social practices that dominate and shape the network society: the space of flows. The space of flows is the material organization of time-sharing social practices that work through flows. By flows I understand purposeful, repetitive, programmable sequences of exchange and interaction between physically disjointed positions held by social actors. (p. 412)

Castells notes, for example, that while people live in places, postmodern power is manifested in the linkages among places, their interconnectedness, as personified by business executives shuttling among global cities and using the Internet to

weave complex geographies of knowledge invisible to almost all ordinary citizens. This process was largely driven by the needs of the transnational class of the powerful employed in information-intensive occupations. Flows thus consist of corporate and political elites crossing international space on transoceanic flights; the movements of capital through telecommunication networks; the diffusion of ideas through organizations stretched across ever-longer distances; the shipments of goods and energy via tankers, container ships, trucks, and railroads; and the growing mobility of workers. In this light, the space of flows is a metaphor for the intense time-space compression of post-Fordist capitalism. Through the space of flows, the global economy is coordinated in real time across vast distances—that is, via horizontally integrated chains rather than vertically integrated corporate hierarchies. In the process, it has given rise to a variety of new political formations, forms of identity, and spatial associations.

Flows by definition involve more than one place; hence, in a networked world, places have little meaning as isolated entities. Places are not locales as much as they are processes in which different types of activities are embedded and different forms of interconnections are established. As they become increasingly connected, the repercussions of actions in one area inevitably spiral out to shape other places, so that discrete boundaries have less and less significance as they are permeated with mounting ease. Decisions made by hedge fund managers in New York, for example, reach out to affect the lives of millions of people in locations as distant as East Asia. The space of flows wraps places into highly unevenly connected chains that center on connections among powerful elites, thus typically benefiting the wealthy at the expense of marginalized social groups. However, the global space of flows is hardly randomly distributed over Earth's surface: Rather, it reflects and reinforces existing geographies of power concentrated within specific nodes and places, such as global cities, trade centers, financial hubs, and headquarter complexes. Thus, far from being abstract networks divorced from history, such systems are only made comprehensible by embedding them in history.

The space of flows is part of a broader conceptual transformation in geography that views space not as discrete places but rather as networks of interconnectiveness. Doreen Massey, for example, promotes a sense of place as embedded within power-geometries that link places to other places, a view in which places constantly change, producing and receiving changes through their interactions with one another. Similarly, Eric Sheppard has argued that globalized power-geometries cut across spatial scales to create “wormholes” that defy the traditional logic of economic geography. Central to such conceptions is the view of space as dynamic, socially produced, and defined by movement. Such arguments point to a relational politics of place that calls into question easy distinctions such as inside/outside, near/far, space/place, and global/local, artificial differentiations that are always embedded in each other and mutually constituted.

SPACES OF REPRESENTATION/ REPRESENTATIONAL SPACES

The terms *spaces of representation* and *representational spaces* form part of the spatial theorist Henri Lefebvre's conceptual triad used to distinguish between different types of spaces and the different ways in which space is produced. Representational spaces, or spaces of representation, as the original *les espaces de représentation* is more commonly translated, is conceptualized as the everyday space that people produce, inhabit, and act within. Similar to the concept of "place," spaces of representation consist of day-to-day human networks, a diversity of urban aestheticization processes, and the complex symbolisms of the underground and vernacular side of social life. The notion of spaces of representation has been used by cultural geographers in thinking about the production of the urban environment as the manifestation of abstract economic processes as well as the location of social and cultural activities.

Although Lefebvre's triad is a Marxian typology of space, spaces of representation resemble the German phenomenological concept of *Lebenswelt*, or the "life-world." Like the life-world, spaces of representation can be thought of, for example, as a composite of the mental maps people carry of their surroundings, the official street signs and place names that provide orientation, and the local graffiti that act as neighborhood landmarks. The unlikely influence of German phenomenology on Lefebvre may be the result of his having read Ernst Cassirer's own tripartite division of spatial experience into organic, perceptual, and symbolic spaces.

Spaces of representation are also called *lived spaces* (*espaces vécus*), as they are simultaneously produced and enacted through experience, expression, contestation, contemplation, sensation, imagination, and sociocultural and biological reproduction. This is not to suggest that spaces of representation occupy a privileged position within a hierarchy of space; rather, spaces of representation should be thought of in relation to, or in dialectical tension with, the other two parts of Lefebvre's spatial triad:

1. Spatial practice, or perceived space: This concept refers to society's organized spaces, which

at once establish and connect different locations through transportation infrastructure, as well as physically and ideologically separate places in the built environment. It can also be thought of as absolute, fixed, and framed space, as in David Harvey's (2006) spatial matrix, or as a material "firstspace," as in Edward Soja's (1996) trialectics of space.

2. Representations of space, or conceived space:

This notion is the abstract, dominant space of a society as conceptualized by planners, technocrats, politicians, and those who wield both power and creative authority. Such authoritative prescriptions for space dictate how environments should look, function, and support particular types of production and consumption. This most closely matches Soja's notion of an imagined "secondspace."

According to Soja, spaces of representation are the outcome of the first two parts of Lefebvre's triad. Soja sees spaces of representation as a summation of all spatial practices and authoritative representations of space. As part of his explicitly political project, Soja gives analytical priority to spaces of representation, as it is in everyday lived space that society can be investigated, understood, and potentially transformed. This critical "third-space," as he calls it, can be viewed as a postmodern milieu of complexity, diversity, and multiplicity. Because spaces of representation are both "real and imagined," they demand a nuanced analysis of both abstract and social production of space and an understanding of diverse spatialities.

While Lefebvre's work, like Harvey's and Soja's, has focused primarily on the urban, spaces of representation can also be thought of as enacted at the global scale, where the First World/Third World and center-periphery dichotomies are confronted, down to the scale of the body, where identity, personal politics, sexuality, and gender are performed.

The perceived holism of spaces of representation has been challenged, albeit tacitly. Geographers have pointed out that depending largely on one's identified class, race, gender, and nationality, it is within spaces of representation that people congregate through open social networks and mutual feelings of belonging and empowerment; and it is from these spaces that people are excluded given the reality of physical barriers, unequal

access to the flow of resources, the uneven distribution of technologies, and the inconsistent recognition of human rights and social justice.

SPATIAL ANALYSIS

Analysis is “spatial” if the results of an experiment or investigation are likely to depend on how the bounding frame of a representation is delineated. A “representation” can be thought of as any kind of simplification of the seeming infinite complexity of reality—as encapsulated, for example, in the ontologies that structure digital representation in geographic information systems (GIS) and geographic information science (GIScience). The frame may be used to bound any space, at any scale, anywhere—so one can conduct spatial analysis of the organs of the human body, for example, or of the canals of Mars. In definitional terms, the realm of *geographical* analysis is somewhat more restrictive in that it pertains to analysis of Earth’s surface or near surface at scales that range from the architectural to the global.

Today, GIS provides the environment for much of the activity that is described as spatial analysis and makes it possible to harness powerful ideas embodied in software to achieve excellence in visual communication. Spatial analysis helps us understand not only the form but also the functioning of physical, environmental, and human systems at any appropriate spatial and temporal scale. As such, it facilitates generalization while also preserving relevant unique attributes of “places” and particular time periods. Paul Longley and colleagues describe how spatial analysis in GIS helps bring together the idiographic tradition in geography (which emphasizes the uniqueness of places) and the nomothetic (which emphasizes the generality of processes), in a science that is directly relevant to practical problem solving. As such, spatial analysis is of interest and applicability well beyond the realm of academia.

Spatial analysis has roots in many sciences, ranging from geography and the Earth sciences to architecture, urban planning, and ecology. Some of these origins can be traced to the development of quantitative methods in geography, macroeconomics, and the Earth sciences, as well as the discipline of regional science. Spatial statistics and locational analysis dominated the quantitative geography of the 1960s, with the development and application of techniques that together laid the foundations of a new scientific geography. These developments culminated in the reader *Spatial Analysis*, edited by Brian Berry and Duane Marble and published in 1968, and the tradition retains a core following in geography today.

The practice of spatial analysis changed profoundly with the advent of the Internet, in line with broader developments in the practice of environmental and social science. The client-server architectures that developed in the 1990s have been augmented by data inputs and feeds to and from the smallest of handheld devices, and the innovation of “sensor webs” has opened up new prospects for spatial analysis based on measurement and monitoring in real time. It has also developed alongside the drives to interdisciplinary science, multidisciplinary team working, and increasingly problem-centered approaches to scientific practice. Yet despite these far-reaching changes, many of the core themes of spatial analysis and modeling remain fundamentally unchanged

from those addressed by quantitative geographers in the 1960s. Of particular importance are issues of spatial and temporal granularity, representation of human behavior, uncertainty in representation, visualization and user interaction, representation of dynamics and spatial process, and policy application through questions of planning and design. These are core to the various research agendas of GIScience.

Representational Forms and Types of Spatial Analysis

Many of the basic operations of GIS—such as distance measurement, area calculation, and map overlay—are not viewed as spatial analysis per se, although software that provides these functions is now the environment of choice for much spatial analysis. Since its development as a field in the 1970s, GIS can also be thought of as providing a series of parallel, yet more application-centered, developments in spatial statistics and locational analysis. Despite the practical applications focus of GIS, there has been methodological interest in integrating some of the more general spatial analysis techniques into GIS software, as a precursor to adoption by the wider user community. By the mid 1990s, more specialized spatial analysis functions had been incorporated into GIS software, and the research communities in modeling and simulation were developing alongside GIS in a more complementary fashion. It also became much more straightforward to couple non-GIS software (e.g., S-Plus, SAS, or Matlab) to GIS, and it is true to say that the boundaries of what may be described as “GIS” have broken down with the incorporation of low-end spatial analysis functionality into general-purpose software such as Microsoft Office. Today, the cutting edge of GIS extends across many fields of spatial representation in modeling, policy, and design, and spatial analysis permeates the GIScience agenda.

There are two fundamental representational models of GIS, and each lends itself to spatial analysis. The *field* view posits space as a series of continuously varying surfaces, each relating to a different attribute—elevation being the archetypal example. As noted by Longley and colleagues, the *object* view conceptualizes the world

as a desktop, littered with objects that have distinct boundaries and attributes associated with them. Attributes of either fields or objects can be thought of as measured using nominal (presence/absence, e.g., of forest land cover), ordinal (ranked, e.g., residential preference), interval (continuous, arbitrary base scale, e.g., degrees Fahrenheit), ratio (continuous, nonarbitrary base scale, e.g., wind direction), or cyclic (directional, e.g., wind) scales of measurement. The locations for which attributes are measured may be described as points (zero dimensioned, having neither length nor breadth, e.g., the locations of individual animals), lines (one-dimensional, e.g., streets), areas (two-dimensional, e.g., agricultural fields), or volumes (three-dimensional, e.g., watersheds). Spatial analysis is defined by its concern with the associations (or lack of them) between the attributes of different locations—that is, the patterning of points, lines, areas, or surfaces as recorded using nominal, ordinal, interval, or ratio scales of measurement.

In measuring associations, methods of spatial analysis may sometimes seek to ascribe causality using the principles of statistical inference—as in the testing of previously formulated theories by comparison with real data. This is the classic deductive style of spatial analysis, the assumptions of which may be strained by the tendency of nearby observations to be more similar to one another than distant ones. A more tentative approach toward measurement of spatial associations is encapsulated in exploratory spatial analysis, which is used to uncover patterns, anomalies, or relationships that may not be immediately apparent and, subsequently, to suggest and support new hypothesized generalizations about the world as a precursor to new theory. This is the *inductive* approach to spatial analysis.

Michael Goodchild develops the following sevenfold classification of spatial analysis, as commonly practiced using GIS, based on the conceptual complexity of the method.

1. *Simple query*: This is the most rudimentary form of spatial analysis, wherein simple queries typically focus on attribute values or attribute value ranges within predefined areas—such as the calculation of the population size of all areas in a study region with unemployment above 7%.

Queries in GIS are frequently formulated in Standard (or Structured) Query Language (SQL)

2. Measurement: This is the use of simple algorithms to measure the length or extent of geographic features in digital representations, as well as properties such as shape, slope, and aspect.

3. Transformation: This entails operations that *buffer*, or dilate, geographic features (as typically represented by points, lines, or areas) to create new features that include all the area within an investigator-defined distance of the original feature. Buffers may be used to calculate the catchment area of a retail center, for example, or the area vulnerable to aircraft noise around an airport. *Spatial joins* are transformations that provide examples of transformations based on shared properties of containment or adjacency, while *polygon overlay* entails computing the intersections between two areas and concatenating the respective attributes.

4. Descriptive summary: This typically entails summarizing the nature of a collection of points, lines, or areas using appropriate statistics. Such summary measures are analogous to aspatial measures such as means, medians, and modes, with the geographic centroid (center of gravity) being perhaps the archetypal example. The spatial analog of the standard deviation or variance is the *dispersion*, defined as the average distance of a set of points from their mean center. *Spatial autocorrelation* measures quantify how similarity of value is related to similarity of position: Positive spatial autocorrelation is characterized by patterns in which neighboring values are more similar than distant ones, with the opposite relationship described as negative spatial autocorrelation. *Fragmentation statistics* may be used to summarize the degree to which an area is fragmented into different land cover types.

5. Optimization: Spatial optimization methods are used to devise idealized patterns that meet user-specified criteria—as in vehicle routing to minimize the distance traveled or location of a store to maximize patronage by likely customers.

6. Hypothesis testing: Confirmatory spatial analysis typically begins with the statement of a null hypothesis, postulating the irrelevance of the effect of interest, and an alternative hypothesis

that accommodates its effect. These conflicting hypotheses are tested against data, and measures are determined that allow the alternative hypothesis to be accepted or refuted. There are difficulties in adapting the classic strategy of statistical inference to spatial data, because some of the assumptions that underpin inferential statistics assume no spatial autocorrelation and because of problems in differentiating between so-called first-order and second-order effects.

7. Modeling and simulation: This approach to spatial analysis seeks to relate explicit theories about the form of the real world directly to data. Thus, for example, hypotheses about the spatial dynamics of city growth and sprawl might be used to drive digital simulations, or an epidemiologist might use a model of day-to-day population circulation to drive a simulation of the diffusion of an influenza epidemic. There is much interest in devising appropriate measures of whether the resulting outputs “look right” in spatial terms as well as in providing comparative numerical summaries of the outcomes of different simulations. This is the fast-developing realm of cellular automata and agent-based modeling, which have been used to simulate residential development and residential segregation, among a wide range of applications.

Conclusion and Prospects

The range of spatial analysis methods described here extends from straightforward descriptive procedures to customized depictions of the world and critical interpretations of the assumptions that are invoked to represent it. The motivation for spatial analysis is frequently the desire to move beyond “what is?” representations of how the world looks toward “what if?” scenario analyses of how the world works. A hallmark of spatial analysis methods is that they should be transparent and open to scrutiny. In recent years, the proliferation of rich, geographically detailed data sets has had the effect of moving the spatial analysis agenda beyond a preoccupation with technique toward embracing ideas about scenario testing, policy, and application. Today, the standard functionality of GIS provides a framework for data manipulation and visualization that,

when harnessed to spatial analysis techniques, provides powerful ways of creating, analyzing, and evaluating policies and plans designed for both the short and the long term.

Some spatial analysis requires very intensive use of computer processing power, and it is true to say that many of the most recent innovations in spatial analysis techniques are among the most computationally intensive. The sheer volume of digital, geographically referenced data makes spatial pattern detection an increasingly important focus, albeit one tempered by the need to understand the sources and operation of the biases inherent in many rich but nevertheless selective representations. There is a continuing need for research into the ways in which the medium of GIS may overwhelm the message of spatial analysis in the eyes of most users, as well as a need for spatial analysts to understand the importance of good user interface design. Much of spatial analysis software is still used on stand-alone machines, but grid-processing architectures are increasingly providing solutions to problems that require intensive processing of diverse data sets scattered across remote locations and that often require different access protocols. Spatial analysis is also extending into the third dimension, in applications as diverse as Web-enabled photogrammetry and location-based services. The miniaturization of computer devices and the innovation of very low-cost radio frequency identification (RFID) is taking some of academic geography back to its roots in field measurement and environmental cognition, and this poses important new challenges for relaying the inputs to spatial analysis to and from the field in real time. This is all part of an unprecedented decentralization of computing, in which data, software, and applications are being distributed across networks and in which spatial analysis is accommodating real-time feeds from sensor webs and other field observations.

Taken together, the networking of spatial analysis has profound implications for the ways in which we may communicate process and visualize spatial data at a range of spatial scales and across a range of time periods. Michael Batty views these changes as part of a paradigm shift from a “top-down,” centralized control to a much more decentralized, bottom-up approach to organization. This is apparent in the ways in which

we now communicate information and expertise about spatial analysis, which was once the preserve of select institutions but is now readily available from online sources (e.g., www.spatialanalysisonline.com and www.spatial-literacy.org). The consequence is an enhanced ability to use spatial analysis to develop richer, more realistic, and more applicable forms of representation that add value and interpretation to geographic data. This is also leading to rethinking of past practices with regard to the conduct of scientific research and is likely to lead to new theoretical imperatives concerning our approach to science in general and GIScience in particular. The evolving spatial analysis agenda is also likely to encounter new practical problems that will affect the way in which we build applications, and the end users for whom we will build them, and new ethical concerns that will determine the way we respond to problems and influence the GIScience that we wish to pursue.

SPATIAL AUTOCORRELATION

Spatial autocorrelation is a spatial measure that evaluates how dispersed or clustered points are distributed in space and whether or not this distribution has occurred by chance. Unlike other spatial methods for detecting spatial patterns of point distribution without considering their attributes, such as Quadrat analysis and the Nearest Neighbor method, spatial autocorrelation also characterizes how similar these points are with respect to their attribute values. There are two typical spatial autocorrelation statistics: Moran's I and Geary's C . Both Moran's I and Geary's C measure the proximity of locations and evaluate the similarity of attributes.

If the statistics show more positive correlation than would be expected from a randomly distributed pattern, points with similar attribute

values are closely distributed in space (Figure 1A), whereas negative spatial autocorrelation statistics indicate that closely associated points are more dissimilar. A chess board is an example of negative spatial autocorrelation (Figure 1B); every black cell is adjacent to white squares, indicating that the neighbors are not similar. Care should be taken when using spatial autocorrelation, as it is related to the scale of the data.

Moran's I can be computed as

$$I(d) = \frac{\sum_i \sum_j w_{ij}(d)(z_i - \bar{z})(z_j - \bar{z})}{s^2 \sum_i \sum_j w_{ij}(d)},$$

where w_{ij} is the weight at distance d such that $w_{ij} = 1$ if point j is within distance d from point i , otherwise $w_{ij} = 0$; $\bar{z}$ is the mean attribute value; s^2 is the variance of the attribute values and can be calculated as $s^2 = \sum_i (z_i - \bar{z})^2 / n$. Moran's I varies from +1.0 for perfect positive correlation to -1.0 for perfect negative correlation.

Geary's C is calculated from the following:

$$C(d) = \frac{\sum_i \sum_j w_{ij}(d)(z_i - z_j)^2}{2 \sum_i \sum_j w_{ij}(d)s^2},$$

where w_{ij} is the weight; s^2 is the variance of z values and can be computed as $s^2 = \sum_i (z_i - \bar{z})^2 / (n - 1)$. The weight, w_{ij} , only considers the values 0 and 1,

Figure 1 Hypothetical images with (A) positive spatial autocorrelation and (B) negative spatial autocorrelation

Source: Author.

Figure 2 Hypothetical images with (A) hot spots and (B) cold spots
Source: Author.

as mentioned above. A typical Geary C value ranges between 0 and 2. A value of less than 1.0 implies positive autocorrelation, 1.0 implies no autocorrelation, and values of greater than 1.0 imply negative autocorrelation.

Similarly, another spatial autocorrelation approach called the *Getis statistic* (G_i) was developed to characterize the presence of hot spots (Figure 2A) and cold spots (Figure 2B), which are sets of clustered points with large or small attribute values, respectively.

The Getis statistic is computed as

$$G_i(d) = \frac{\sum_i \sum_j^n w_{ij}(d) z_i z_j}{\sum_i \sum_j^n z_i z_j}, \quad \text{for } i \neq j.$$

The G_i is also defined by a distance, d , within which areal units can be regarded as neighbors of i . The weight $w_{ij}(d)$ is 1 if areal unit j is within d and is 0 otherwise. Some of the z_i, z_j pairs will not be considered in the calculation of the numerator if i and j are more than d away from each other.

SPATIAL COGNITION

Spatial cognition concerns the acquisition, management, and application of knowledge about phenomena in the physical world. Humans derive this knowledge from internalized processes within the cognitive system, which is believed to reside within the mind. As such, spatial cognition is intertwined with processes of

thinking, reasoning, memory, abstraction, problem solving, belief formation, perception, sensation, language, and representation related to the spatial properties of objects and events situated in space. The main distinction that can be drawn between cognition and spatial cognition is the focus on the spatial properties of objects and events in spatial cognition.

Geographers interested in spatial cognition mainly focus on the domain of human beings. In other disciplines, spatial cognition also explores cognitive aspects in the context of nonhuman animals. In fact, Tolman's article (1948) on the maze behavior of rats is commonly referred to as the foundation stone of research in spatial cognition. Traditionally, spatial cognition as a field of investigation has been pursued interdisciplinarily by researchers from diverse academic disciplines such as psychology, geography, architecture and planning, anthropology, information science, linguistics, computer science, artificial intelligence, and neuroscience. Theory has been primarily derived within psychology. For instance, one prime example for the psychological tradition in spatial cognition is the work of Jean Piaget and Barbel Inhelder on the acquisition of spatial knowledge by children, published in 1967. Another example is A. W. Siegel and S. H. White's 1975 article on the sequential acquisition of spatial knowledge in adults in terms of landmarks, routes, and survey knowledge. The particular research topics in spatial cognition are just as diverse and include, among others, spatial representations and cognitive maps; orientation, navigation, and wayfinding; learning of familiar and unfamiliar environments; and gender and age differences in spatial abilities.

Cognitive Maps and Cognitive Mapping

At the core of research in spatial cognition lies the urge to understand the internal spatial representations that emerge in animals and humans through interaction with the physical world. That is not to say that spatial representations are merely created through stimulation of the body's senses. Instead, they can also entail derivatives of the imagination that are evoked through activities such as reading novels, listening to songs, and participating in discussions. As noted before, we

observe that geographers focus on humans as the subject of their research (as opposed to animals and intelligent machines) in their drive to understand human decision making in space.

Spatial representations stored in the long-term memory are referred to as *cognitive maps*. First coined as "mental maps" by Peter Gould in 1966, various metaphors have been proposed to describe what a cognitive map is. A noncomprehensive list would consist of Gould's preference surface metaphor, the rubber sheeting metaphor used by Reginald Golledge, the cartographic map or atlas metaphor, and the belief system metaphor.

The expression *cognitive map* often evokes the idea of a cartographic map in people who are not familiar with the meaning of the expression. It is generally accepted, however, that a cognitive map is quite distinct from a cartographic map. Rather than adhering to a single metaphor, it is more likely that a cognitive map incorporates elements of many or all of the aforementioned metaphors. At any given time, a cognitive map entails information about the physical and imagined environments that the individual has experienced. Since the information is dependent on experience and knowledge, both of which are changing over time, a cognitive map can be seen as a dynamic collection of heterogeneous spatial and nonspatial information about the environment that the individual has acquired through interactions with it.

Rather than a homogeneous, indivisible structure, a cognitive map is a set of discrete pieces of knowledge, both explicit and implicit. The pieces show varying levels of distortion, abstraction, and incompleteness. Besides spatial information such as the location of landmarks, the trajectories of routes, and the distance and direction relations between spatial features, a cognitive map also includes individual and subjective components such as emotions, values, and beliefs. The corresponding process of acquiring, storing, manipulating, deriving, and accessing a cognitive map is referred to as *cognitive mapping*.

The first and most prominent application of the concept of the cognitive map can be found in Kevin Lynch's famous book, *The Image of the City* (1960). Lynch elaborated on the externalization of the spatial knowledge of adults with regard to urban environments. In particular, he asked adult residents of Boston, Jersey City, and Los

Angeles to draw sketch maps of their home cities. Out of the individual sketch maps, Lynch created composite maps for each city of the features that were captured by the majority of subjects. He identified five types of elements of a city layout that were evident in the sketch maps: paths, edges, districts, nodes, and landmarks. The term *legibility* was coined to express the importance of the arrangement of these five components for their integration into an encompassing representation of the city. The more legible a city, the easier it is for the individual to understand, memorize, internalize, and organize the city into a cognitive representation, or cognitive map. Lynch's main finding was that the subjects formed cognitive representations that were quite similar for the majority of subjects—an indication that cognitive mapping is a rather universal process that applies to the general population.

Spatial Knowledge Acquisition

Lynch's analysis sparked further interest in the similarities and differences in the development of cognitive maps and the acquisition of spatial knowledge. Research on spatial knowledge acquisition was strongly influenced by Piaget's developmental theory, proposed in 1967 by Piaget and Inhelder. The theory maintains that children acquire spatial knowledge sequentially through four stages of their childhood: (1) the sensorimotor stage (0–2 yrs. [years]), (2) the preoperational stage (2–7 yrs.), (3) the stage of concrete operations (7–11 yrs.), and (4) the stage of formal operations (11 yrs. and above).

Similarly, Siegel and White introduced the theory of *macrogenesis* in 1975. Macrogenesis suggests that adults learn about a new environment in three stages. First, they develop knowledge of salient places or landmarks in the environment. This type of knowledge is commonly referred to as *landmark knowledge*. Subsequently, through further exploration, the individual gains topological and metric knowledge—that is, the distance and direction relations between landmarks—and establishes linear connections, or routes, between landmarks. This type of knowledge is referred to as *route knowledge*. Finally, indicating the greatest familiarity with the environment, the individual gains understanding that allows him or her to

venture away from known routes by detouring and shortcutting. Detours and shortcuts necessitate an integrated, areal type of representation of the environment, or *survey knowledge* as termed by Siegel and White. Significant in this context is the progression from an *egocentric* frame of reference with a primarily nonmetric, topological representation to an *exocentric* frame of reference with a metric, configurational representation of the environment.

Spatial Abilities and Individual Differences

The cognitive maps of the participants in Lynch's analysis showed significant similarities based on the taxonomy that he applied. After all, the subjects were all able to reproduce more or less detailed configurational depictions of their home city. Individual spatial representations and abilities, however, are far from equal. This is not surprising since, as mentioned before, spatial representations, skills, and abilities are informed by spatial knowledge that depends on the individual's experience with the environment. This experience is shaped not just by the specific physical characteristics of the individual but also by sociocultural factors—how we were raised, what our job is, what hobbies we have, and who our friends are. For example, given the same city, the extent of the activity space (i.e., the set of all places that an individual frequents as part of his or her daily life) of low-income, blue-collar workers is generally very different from that of their high-income, white-collar peers.

Vision, considered the spatial sense per excellence, plays a central role in how we experience the world. A single glance around us provides us with a multitude of information that can be used as source for spatial decision making. For navigation purposes, for instance, we can use distant landmarks in combination with feature-matching techniques to determine our location on a map. Salient landmarks can be easily identified and used as directional beacons. A visually impaired individual, however, has only limited or no access to this information. Tasks such as orientation become much more constrained by comparison with sighted individuals. In this context, research has shown clear differences in terms of the performance of the sighted and the visually impaired

in various areas related to spatial cognition, especially with respect to *spatial updating*. Various studies also reported on performance differences between congenitally and adventitiously blind individuals. Having prior visual experience resulted generally in improved performance of the individual in terms of accuracy and the time needed to complete spatial tasks compared with individuals with little or no visual experience.

The aspect of gender has been operationalized in research on the spatial abilities of men and women. In research on mental rotation skills, as one type of spatial skill, men were found to perform better than women. Research on the way-finding abilities (e.g., pointing accuracy) of males and females, on the other hand, has not produced significant differences between the genders. It is generally accepted that gender differences in regard to spatial abilities are specific to the task and testing procedures rather than evidence of the superior physiological disposition of men for all things spatial. It is also unclear to what extent gender differences in spatial abilities are the result of processes of social conditioning that emanated over long periods of time as manifestations of traditional gender roles (e.g., hunters and gatherers). Apart from gender, geographers also explored notions such as race, class, attention, effort, distortions, and bias and their influence on the spatial cognition of the individual.

Recent Research in Spatial Cognition

Over the past few decades, spatial cognition research has gained momentum through the significant proliferation of technology. The Internet, as a prime example, has irreversibly transformed the way we retrieve information and communicate with other people. Cartographic applications such as Google Maps and Google Earth are available free of charge, providing new ways of experiencing and learning about the environment to vast parts of the population. In this context, many interesting research questions emerge: What is the best way to present (spatial) information? How can we improve our user interfaces so that the usability of a spatial technology is maximized? How does the use of spatial technologies influence the user's spatial representations, skills, and abilities?

Clearly, a thorough understanding of the underlying cognitive processes can inform new approaches and practices that are tailored to the expectations and information needs of the user. In addition, such understanding might be used to minimize the cognitive load that is associated with the use of a particular technology—cognitive efficiency as a new design paradigm. A noncomprehensive list of related research topics that are being investigated in geography includes geovisualization, information visualization, and spatializations; pedestrian and car navigation systems; naive cartography, geographic information systems (GIS); and volunteered geographic information; location-based services and mobile computing; ubiquitous computing; artificial intelligence; and robots. It is likely that the importance of spatial cognition will grow with the further dissemination of information technologies in our society.

Little theory exists in regard to the design and evaluation of applications intended as decision-making aids for lay users. Research on public participation GIS (PPGIS), for instance, requires further exploration of the merits of using these tools in participatory planning processes. If our goal is to create inclusive, empowering tools with the intention to offer all users the means to make good decisions, then we need to establish an understanding of the expectations and information needs of each individual user. In addition, we should reflect on the criteria that we use to evaluate such decision-making tools. One common approach is to ask the user for his or her feedback on the tool. Ease of use, the mode and style of the presented information, and the beliefs and emotions of the user in regard to the information and the tool are all aspects that influence the user's assessment of the tool. Research on spatial cognition can provide valuable insight into many of these aspects. As stated earlier, spatial cognition is about understanding how people encode, store, access, and use spatial information. If 80% of all our decisions involve spatial information, then research on spatial cognition is central to understanding and enhancing our decision-making processes—most of which are central to our daily life.

SPATIAL COGNITIVE ENGINEERING

The goal of spatial cognitive engineering is to design spatial information systems and services based on the principles of human communication and reasoning. It is an interdisciplinary endeavor, involving the disciplines of geographic information science, cognitive science, computer science, and engineering. A special focus is human-computer interaction based on the integration and processing of the spatial and temporal aspects of phenomena. The field of spatial cognitive engineering is motivated by the belief that useful and usable solutions to people's geospatial problems can only be found by considering the cognitive abilities and strategies people bring to the problem-solving process.

Roots: Cognitive Engineering

The term *cognitive engineering* was invented by Donald Norman in an effort to integrate cognitive and computer science approaches to the design and construction of machines. According to Norman, cognitive engineering is a type of applied cognitive science. When looking at people's interaction with different everyday things, such as telephones, faucets, and doors, one notices a discrepancy between *psychological user variables* and *physical system variables*. The psychological user variables comprise goals, intentions, concepts, and also spatial and cognitive abilities. During the performance of a task, a user must therefore interpret the physical system variables in the context of his or her psychological goals and translate his or her psychological intentions into physical actions on the system. The goal of cognitive engineering is to bridge the so-called gulf between execution and evaluation (Figure 1), which results from the differences between user and system states in terms of form and content.

This gulf can be bridged from two sides:

1. The system designer can move the system closer to the user in terms of finding better matches to his or her psychological needs.
2. The user can bridge the gap by approximating the description of goals and intentions to the system's language. Such approximation covers different levels of outcomes and intentions.

In his account of cognitive engineering as a new discipline, Norman focused on computer design in general and the design of user interfaces in particular. A major point in the analysis was that different users may require different interfaces, even when performing the same tasks and working with the same system. He therefore advocated a *user-centered* system design, which starts with the user's needs regarding a particular problem.

From Cognitive Engineering to Spatial Cognitive Engineering

Spatial cognitive engineering follows the general ideas of cognitive engineering and applies them to the geospatial domain. Such application highlights important aspects that are integral to and

Figure 1 Discrepancy between psychological user variables and physical system variables

Source: Adapted from Norman, D. (1986). Cognitive engineering. In D. Norman & S. Draper (Eds.), *User centered system design* (pp. 31–61). Hillsdale, NJ: Lawrence Erlbaum.

characteristic of geospatial problem solving. Spatial cognitive engineering focuses especially on human-computer interaction regarding the *spatial and temporal aspects* of phenomena in the world. Geospatial services and systems are unique in the way they use data, which are related to locations in space (and time), and in how processing of the data with respect to these spatial locations is possible. The fact that everything is tied to a location in space and time leads to increased complexity regarding reasoning with and analysis of the data. People's questions when using geospatial tools have a spatiotemporal context. One can ask "Where is (a certain object)?" or "Where

are (all objects with certain properties)?" at a given time—for example, when trying to find the nearest kindergarten for a child; or one can ask "What are the properties of (a certain area in space)?" at a given time—for example, when trying to assess the area in which to rent a house.

Resolving the discrepancy between psychological user variables and physical system variables in the geospatial domain goes beyond the user-interface level:

- People use various conceptualizations of space and time, such as "continuous versus discrete" or "absolute versus relative." The particular

spatiotemporal perspective in spatial cognitive engineering implies that spatial and temporal concepts need to be matched between users and systems. Take, for example, the different semantics of spatial concepts, such as location or road, depending on the user and context. Semantic heterogeneity—two contexts leading to different interpretations of the same information—can lead to erroneous decisions made by geospatial services. The results of a spatial analysis may be correct for the data model of the data set but may still not meet the user's expectations and can therefore lead to false decisions.

- Spatial reasoning and decision making in a spatiotemporal context include particularities that need to be accounted for during human-computer interaction. Spatial reasoning is about topology, distance, orientation, and shape with regard to objects and configurations of objects in space and time. Instead of doing exact calculations, people apply qualitative methods of spatial reasoning that rely on magnitudes and relative values—see, for example, the differences between wayfinding instructions as given by humans versus machines. When people perceive space through different channels, they arrive at various kinds of information, which are usually qualitative in nature. People do not move through the environment using rulers or tape measures. Spatial reasoning involves a variety of decision-making methods and choice behavior. In many cases, human decision making is not strictly optimizing in an economical and mathematical sense as proposed by the algorithms of classical decision-making theories. Several of these aspects are accounted for to various degrees during spatial cognitive engineering.

Cognitive User Parameters

When dealing with the problem of considering people's spatiotemporal and cognitive strategies and abilities during their interaction with geospatial services, it is of major importance to account for people's problem-solving requirements. These requirements differ, depending on the category of user. With regard to the acquisition, mental representation, use, and communication of geographic

information, it has been argued that information consumers differ in their cognitive styles, abilities, and preferences. Cognitive research helps understand how individuals and groups of people differ in their cognition of geographic information. Several case studies involving the cognitive aspects of navigation systems demonstrated the importance of taking into account individual differences among navigators, such as different abilities, preferences, and navigational styles. The importance of research on education, experience, culture, gender, and age differences has been emphasized in efforts to design better—in the sense of more *personalized*—geospatial tools.

Users can be categorized into *generic*, *group*, and *individual* with regard to their cognitive parameters, such as strategies, abilities, and concepts. The generic level comprises a general set of cognitive parameters assumed to be applicable to all people. For example, in general, people use landmarks for finding their way and for communicating wayfinding directions to others. The generic category also accounts for the fact that there are numerous cultural universals that people share. User groups are defined by common sets of cognitive parameters. The focus of analysis is on the variation of parameters across different groups. Examples are gender groups, such as all women and all men, and comparatively smaller cultural groups defined, for example, by sharing a common language. These examples demonstrate that user groups occur at different levels expressed through the number of their members. User groups are often defined for user interface design—for example, novice versus expert. Wayfinding services may distinguish between different groups of disabled (e.g., visual or hearing impaired) persons. Wayfinding instructions need to be adapted to these groups to be useful. Dealing with people as individuals puts a focus on individual variation. Every single person is treated differently. Personalization of geospatial services can go a long way; the more parameters there are that need to be adapted, the more complex it becomes.

It is useful to note that this classification forms a hierarchy (Figure 2).

All people share some cognitive parameters, but they also fall into various user groups and have their individual preferences. When using spatial cognitive engineering approaches for the

Figure 2 User categorization into generic, group, and individual

Source: From Raubal, M. (2005). *Cognitive engineering for geoinformatics*. Solingen, Germany: Verlag Nature & Wissenschaft.

design of geospatial services, a major question is, therefore, how far one can or wants to move down in this hierarchy.

Applications

Spatial cognitive engineering has been applied in various areas to bring geospatial tools closer to the user, with respect to both monolithic geographic information systems (GIS) and geographic information services. Lately, research has focused on personalizing location-based

services—information services that are sensitive to the location of a (mobile) user—with the goal of creating *location-based decision services*, which support people's everyday spatiotemporal decision making in a mobile context. The following selective list gives some examples of applying spatial cognitive engineering:

- Spatializing user interfaces to map the particular spatial experiences of users to various application domains: Considering how individuals understand and represent space

benefits the design of GIS and facilitates user interaction with these systems.

- Designing natural-language query interfaces for GIS: Such interfaces allow users to pose their spatiotemporal questions in a more natural way.
- Developing personalized navigation services that offer wayfinding directions based on landmarks: These services also consider user preferences for the performance of spatiotemporal tasks.
- Applying cognitive design principles to cartographic maps and geographic visualizations to facilitate people's understanding and knowledge acquisition
- Designing geospatial tools for disabled people, such as global positioning system (GPS)–based navigation systems for the visually impaired

SPATIAL DATA INFRASTRUCTURES

A spatial data infrastructure (SDI) is an infrastructure for integration, transportation, and distribution of spatial data via Web services using service-oriented architectures (SOA) and business process patterns. Therefore, it supplies applications with spatial products. A product might be a data set, a service, or a combination of the two.

This entry describes the characteristics of the payload spatial data, gives a historical context, introduces roles and fundamental processes, and illustrates them with technical example architecture, including data, query, and service models.

Characteristics of Spatial Data

Spatial data can be used for many different purposes due to their special characteristics. Like other types of data, spatial data can be encoded digitally and transported via the Internet. But also, in many cases, they can be displayed graphically, making the information easier to interpret and understand. However, there are other characteristics of spatial data that need to be managed before one makes use of them. Many organizations capture spatial data but often in quite different ways and for many purposes. A single organization may capture spatial data for a limited part of the world—for example, a national mapping agency; therefore, spatial data from many organizations must be combined to ensure worldwide coverage. Furthermore, often these spatial data have a short shelf life and therefore will become outdated in a short period.

Due to these special characteristics of spatial data, an efficient integration, transport, and distribution mechanism is crucial to enhance their overall usage. The geospatial information sector identified this potential very early and pushed the development of spatial data infrastructures. SDIs are one of the first large applications of information infrastructures based on Web services.

History

In the early 1990s, these spatial data characteristics resulted in many incompatible solutions.

Early developments focused on the creation of a standard and vendor-neutral data model to encode and exchange spatial data. These efforts were channeled via the founding of the OpenGIS in 1994, which is known today as the Open Geospatial Consortium (OGC). Major milestones since then were the formulation of the U.S. national SDI by the Federal Geographic Data Committee and the first Global SDI conference, GSDI 1, in Bonn, Germany, in 1996. Parallel developments within the World Wide Web and the Internet added a new capability to call remote functions, which are known today as *Web services*. In 2000, the popular Web Mapping Service specification was released by the OGC. As a result, many local, regional, national, and supra-national SDI initiatives were founded. In 2007, the European Union (EU) enacted into law the INSPIRE (Infrastructure for Spatial Data in Europe) directive, together with a long-term roadmap for the implementation of this law running until 2015 and beyond. The law defines 34 spatial data themes, some for geospatial reference data, and other themes needed to support health, agricultural, urban, and environmental applications. It requires public bodies within each of the 27 EU member states to provide data relating to spatial data themes as a set of services for use by institutions and organizations in the EU.

As the development of SDIs is a work in progress, this entry can describe only the current state of the art. Many of the key concepts behind SDIs are stable, while others are evolving.

Roles and Responsibilities

All infrastructures need to support different kinds of users. Different users have different responsibilities, and these can be classified into different roles. Interestingly enough, many infrastructures, for example telecommunication, electronic banking, and public utilities, show very similar roles and responsibilities, even though the actual products that are consumed are physically very different.

A key relationship is between the roles of SDI service customers and SDI service providers. Another key relationship is between SDI service providers and SDI committees. Contracts may be used to formalize these relationships. Some roles

could be assigned to departments within the organizational borders, whereas other roles could be subcontracted to external organizations. Many providers may subcontract roles, with their associated responsibilities, to the same organization, allowing for economies of scale. Users with defined roles are able to interact within a defined process model to find each other and to finally transfer products. Figure 1 shows the role definitions and their relationships. This entry does not describe the secondary roles in detail. The introduction of a new product must involve all the following elements: (1) correspondence to SDI customer requirements, (2) a contract for an information product (IPR) from an IPR owner, (3) setting up of the business network, and (4) setting up of registers (e.g., if unique identifiers [IDs] are required or common data schemas are used). After this initialization process, potential SDI service customers can find, agree on, and bind the new product, serving the final domain end user via the domain service provider.

SDI Committee

The operation of a multiprovider infrastructure network requires a body to handle SDI-wide issues, for example, unique IDs or spatial data application schemas. To balance sensitive interests, this committee should consist of SDI service providers.

SDI Service Provider

A provider is a commercially responsible party, carrying the full business risks. To enlarge a product coverage, a provider may establish an agreement with other providers to share their networks (roaming agreement), without losing any market appearance. A provider may enhance his or her offer by contracting additional resources from IPR owners. A provider also takes care of advertisement, establishment, and maintenance of customer accounts and delivery.

SDI Service Customer

A customer establishes a contract with a provider to use products. A customer may be a public organization or private entity, for example, a for-profit company. In many cases, this role is carried together with the domain service provider's role for a spatially enhanced domain-specific product.

Figure 1 Role model with key relationships and secondary roles

Source: Author.

Process Model

The shift from a closed (desktop) to a distributed (Internet based) environment and therefore from a single- to a multiple-user environment required a process model to allow an ordered interaction between potentially unknown actors. The fundamental business process has four sequential phases. Some phases may be implemented as automated processes, whereas others may be

implemented as manual processes. The process phases and their interactions are shown in Figure 2.

Publish

In the first phase, a new product involving spatial data sets and/or services is published for usage by an SDI service provider. Also, a centrally administered and therefore reliable publication process assigns unique IDs to providers, spatial

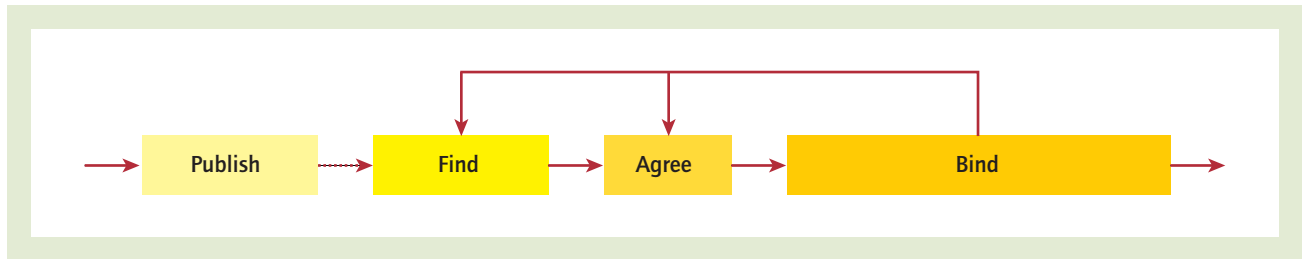

Figure 2 Fundamental SDI process model

Source: Author.

data application profiles, coordinate systems, and license categories. For data sets and services with SDI-wide impact, the registration and maintenance is done by an SDI committee. Otherwise, the publication is done via a product catalog by an advertiser. The result of this process phase is the published product description.

Find

After a product is published, an SDI service customer may find a product by querying the product catalog. In addition, automated applications may search the same product catalog with predefined queries for a given product type—for example, for a specific geographic location. The product description provides some additional information, for example, how to access it, and linking information for the agree-and-bind phase. An advertiser operates a product catalog.

Agree

In general, the establishment and maintenance of contracts between an SDI service customer and an SDI provider is handled in this phase. In a professional SDI, the interest between IPR owners, SDI service providers, and SDI service customers needs to be expressed and agreed via explicit contracts to avoid legal disputes. Alternatively, implicit contracting by declaration of usage rights given in the product description is also possible. In this case, the agree phase might be omitted. This applies also in the case of manually established contracts. Parts of this phase are handled by the sales and account manager roles, acting on behalf of an SDI provider.

Bind

The delivery of spatial products, data, or services is the subject of this phase. There might be contract preconditions prior to access. Therefore, a rights management layer needs to be passed, for example, to check access credentials or to report account usage to the assigned account manager. Different SDI services, for example, for visualization (Web Mapping Services), querying, and downloading (Filter Encoding and Web Feature Service); for transformation; and for process chaining, can be used in this phase. The automated components are described in the following section in detail. This phase is operated by a delivery function acting on behalf of an SDI service provider.

Cascading

Another basic process of integrated distributed services is cascading. A service instance may be implemented on the service side as a collection of multiple services. A received request will be separated according to the distributed services, which are called separately. The responses will be integrated and delivered; that is, two layers will be overlaid and delivered as a single image. Cascading ensures the integration of multiple services within an SDI and also between SDIs. Therefore, it is a fundamental process, which is illustrated in Figure 3.

Architecture Model

The described roles interact via the described business process model. This process may be supported by electronic components. Therefore, a technical architecture shows the derived components. Figure 4 depicts the INSPIRE architecture

Figure 3 Cascading

Source: Author.

with INSPIRE abstract terms, with the publish phase marked as not finalized yet. Multiple tiers include group service, data, and data schema components. The application tier is undefined because of different domain-specific usage. Geoportals can be used to view spatial data, as with a classic atlas. Between the application and the general service tier, a rights management tier may be used to handle rights issues. The service tier interface is well-defined via standards. The data tier stores data. The thematic spatial data application schema tier defines the structure.

Data Models

Currently, the data models for spatial data and for product description (metadata) have been defined. Most SDIs use the OGC's XML (Extensible

Markup Language) dialect, called *Geographical Markup Language* (GML), although other data schemas, for example, KML (Keyhole Markup Language), might be used. GML aims to offer a set of spatial objects. It separates *model* from *view* and does not offer visualization capabilities. OGC symbology encoding (SE) was specified to define the visualization. Due to this GML characteristic, a GML application schema needs to be derived and named. To enhance exchange capabilities, thematic communities should develop these schemas according to their needs. These schemas should be registered to SDI committees to ensure wide and cross-thematic usage.

The product description is standardized as metadata. ISO 19115/19139 defines the metadata encoding for spatial data. ISO 19119 defines the metadata encoding for services. Due to the wide range of potential descriptions of thematic data and services, the volume of a product description may vary from 18 to 400 elements.

Spatial Operators and Query Language

Spatial information has a spatial reference given by a reference system, which can be described and accessed with mathematical methods. These basic mathematical formulae can be combined into higher-level spatial operators. The following spatial operators representing topological relationships are defined: Equals, Disjoint, Touches, Within, Overlaps, Crosses, Intersects, and Contains. Spatial operators can be combined with logical and relational operators, mathematical expressions, and functions to define a query language. This powerful language is called *OGC Filter Encoding* (FE) and allows spatial and nonspatial analyses of data. It is used to query the product catalog service (discovery service) and the Web feature service.

Service Models

The Internet offers, in addition to digital data transport, remote function calls, which are called operations of Web services. An operation can accept input parameters allowing user-defined on-the-fly production. Web service components are designed to support the business process depicted in Figure 1. Figure 4 shows the service components included in the service tier. These

Figure 4 INSPIRE architecture, including “agree” phase

Source: INSPIRE Drafting Team Network Services.

components, which support the process model phases, are described below in detail.

Because the function of register for the publish phase has not yet been defined, no specification for an electronic component is available yet.

The find phase can be supported with a discovery service (catalog service) for search together with the described metadata models and the filter encoding query language. Because of performance

issues and structured search, only a subset of metadata can be queried. A free text search via all data fields is possible, and typical search functions are supported. The results can be listed in a very short, medium, or full set. Also, the results may be limited per request to allow proper visualization. Multiple service profiles are defined to support different thematic domains. Automated search, for example, for the next valid service

Figure 5 Integrated view of described roles and processes in INSPIRE architecture, including the “agree” phase

Source: Adapted by author from INSPIRE Drafting Team Network Services.

type instance, is also allowed. In the transactional mode, the read and write functions, such as delete, update, and store, are supported.

The agree phase needs services to support the establishment of contracts and management of accounts. Functions for pricing, licensing, and access control are needed. Other business functions, for example, watermarking, might be subjects for future developments.

The delivery phase enfold multiple content and processing services. Specific definitions vary among SDI initiatives and may depend on the providers. INSPIRE defines on an abstract level *view*, *download*, *transformation*, and *invoke* service types. On an applied level, these categories fit the OGC Web Mapping Service (WMS), OGC Web Feature Service (WFS), and other upcoming OGC specifications.

Roles, Process, and Architecture Overview

The described major components of spatial data infrastructures are related to each other. Although many different constellations are possible, Figure 5 illustrates an example of an integrated model of SDI.

SPATIAL DATA INTEGRATION

Spatial data integration is the process of making data from different sources compatible so that they can be used appropriately in an analysis framework. Before spatial data can be viewed, queried, combined, or analyzed, the integration process must address the many ways in which they can differ in terms of the following:

Content: The type of geographic feature or phenomenon represented and the properties used to describe it

Spatial representation: The conceptual model of space (object or field view), spatial data model (vector or raster) and spatial object type (point, line, polygon, cell), or indirect spatial reference (place name or code) used to identify location

Spatial reference: The coordinate system (datum, map projection or coordinate system, and units), geographic extent, and spatial resolution of the data or the source scale of any mapped data inputs

Attributes: The measurement scales, units, terminology, and classification systems

Time frame: The date or data range of acquisition or last update

Data/file format: The format used to encode the data, for example, GML, KML, shapefile, ascii grid, and tiff

Data quality: Attribute and positional accuracy, logical consistency in the geometric and attribute data, and data completeness

Lineage: The means by which the data were acquired, including instruments, calibration, sampling or enumeration strategies, protocols, and processing steps

Purpose: Who collected the data, why, and what, if any, are the restrictions on its use

The three types of spatial data integration tasks are temporal, horizontal, and vertical integration. *Temporal data integration* refers to combining similar data sets collected at different times for the purpose of change detection or to create an updated data set. Horizontal data integration involves the merging of adjacent data sets to create a new data set with a larger geographic extent. Vertical data integration is an essential first step in spatial overlay analysis and has the widest application.

The primary goal of spatial data integration is to use multisource data analysis to support better understanding of existing conditions, relationships, and trends, which in turn should lead to better spatial decision making. Related objectives are to improve the efficiency and quality of information extracted from multiple sources, whether these data are integrated to create new information or to reduce data volume and redundancy. A number of factors are driving the need for sound integration principles and practices. First, because spatial data are often expensive to produce, analysts use a variety of heterogeneous data sets that they did not produce in applications other than those for which the data were intended. Second, technological changes have led to an exponential growth in the type, amount, and availability of spatial data, which in turn has led to an increase in the number of users of and applications for these data. Third, an enormous amount of legacy data exist that could be used for richer temporal analyses. Finally, there is a growing demand for online access to distributed, heterogeneous spatial data; this is often referred to as *interoperability*, due to the need for both data- and systems-level integration.

Two key factors critical to a successful integration process are metadata and spatial data quality

assessment. Metadata, or information about the data, provide information that identifies a data set and documents its characteristics (identified above). Significant problems with spatial metadata include nonstandard metadata, poorly completed metadata, and incomplete or a complete lack of metadata. Assessing the quality of spatial data integration inputs and outputs is critical to maximizing their effectiveness. Spatial data quality is typically discussed in terms of error and uncertainty. Errors are deviations from “true” values in positional or attribute measurement or in category assignment. Since true values are often not known, uncertainty is a broader term used to describe the ways in which a digital representation varies from the real-world geographic object it describes and includes the notion of error, inaccuracy, vagueness, and ambiguity. Measuring errors and uncertainties, determining how they propagate in the spatial data integration process, and assessing the range of quality levels that can be tolerated for specific analysis tasks constitute an important and active research area.

Many of the spatial data integration strategies that have been developed are ad hoc—designed for specific projects and data and performed with little automation. Current efforts to generalize the process include standards and framework data. Agencies such as the U.S. Federal Geographic Data Committee (FGDC), the Open Geospatial Consortium (OGC), and the International Organization for Standards (ISO) are developing standards for spatial data collection, representation, and metadata. FGDC standards include wetlands and vegetation classification systems, content standards for cadastral data, digital orthoimagery, remote sensing swath data, utilities data, metadata, and so on. Standards improve the process of spatial data integration by providing a consistent means for comparing data content and quality. The FGDC is also spearheading the development of the National Spatial Data Infrastructure (NSDI), which includes a framework of the seven most commonly used geographic data themes: geodetic control, orthoimagery, elevation, transportation, hydrography, governmental units, and cadastral information. These data, and related procedures, guidelines, and technology, facilitate integration by providing reference data that spatial analysts

can use to accurately register and compile other data sets or display the locations and the results of their analyses. Additionally, emerging research on geospatial semantics suggests the use of ontologies (domain-specific semantic networks) as a tool for automating spatial data integration.

Spatial data integration is powerful because it allows for more insight than what could be obtained by examining the data separately. However, problems associated with the many ways in which spatial data can differ create major impediments to their appropriate integrated use. Although aspects of spatial data integration are improving and advancing our understanding of underlying issues, current approaches have not kept pace with the increases in spatial data and the applications for their use. The University Consortium for Geographic Information Science (UCGIS) has identified specific research priorities as well as the need for a general theoretical and conceptual framework for spatial data integration.

SPATIAL DATA MINING

Scientific understanding of geographic phenomena often depends on the collection, analysis, and interpretation of observational data. With increasingly powerful and spatially enabled data-gathering techniques, such as remote sensing, census survey, global positioning system (GPS), and sensor networks, large volumes of geographic data are being accumulated at an unprecedented speed in many application domains, including climatology, public health, environmental science, business, and transportation, among many others. These data hold great potential to provide valuable and previously unknown information to understand and solve complex real-world problems. However, it is a great challenge for researchers to discover new knowledge from such large and complex data sets.

During the past decade, knowledge discovery and data mining have quickly become active research areas that span many disciplines, focusing on the development and application of new analysis methods to extract nontrivial and potentially useful information from large amounts of data. Data mining usually involves multiple steps, such as data preprocessing, transformation, analysis, human interaction, and result interpretation. In general, there are two main challenges for data mining research: (1) the discovery of complex, unknown, and even unexpected patterns (which traditional methods cannot find) and (2) efficient extraction of information from very large databases (whereas traditional methods are often computationally expensive and can only deal with small data sets. Common data mining tasks include clustering (unsupervised classification), supervised classification, prediction, association rule mining, temporal trend analysis, outlier detection, and multimedia analysis, among many others. For each task, there are different methods, which can be computational, statistical, or visual.

General-purpose data mining methods, however, cannot fully address the unique challenges related to the analysis of geographic data. Spatial data have a number of characteristics, including spatial autocorrelation, spatial nonstationarity, complex geographical relations and constraints,

high dimensionality, unique spatial pattern types, and various application-specific requirements. General-purpose data mining methods are not able to consider these spatial characteristics and are therefore ineffective in discovering meaningful geographic information. On the other hand, traditional spatial analysis methods, such as spatial statistics, often focus on a specific type of pattern (e.g., spatial autocorrelation) and are only able to analyze small data sets. There is an enormous need for new approaches that are more effective than traditional approaches in turning the wealth of spatial data into valuable information.

Spatial data mining focuses on the development of efficient and effective methods to extract useful information and knowledge from massive spatial databases. Existing methods for spatial data mining span three main groups: *computational*, *statistical*, and *visual approaches*. Computational approaches resort to computer algorithms to search large volumes of data automatically for specific types of patterns, such as spatial clusters, spatial association rules, homogeneous regions, colocation patterns, and spatial outliers. Statistical approaches include spatial scan statistics, geographically weighted regression, multivariate lattice models, and spatial association tests. There are also numerous visualization-based methods for multivariate spatial analysis, such as multivariate mapping, spatiotemporal visualization, and other interactive geovisualization techniques.

Although computational and statistical methods can search for a specific type of pattern very quickly, they have very limited capabilities to support pattern interpretation. In contrast, visualization methods can help humans visually discern complex patterns, propose explanations of the observed patterns, and generate hypotheses for further analysis. To combine the advantages of different approaches, integrated methods have been developed to bring together the computational and visual approaches in order to address complex problems more effectively.

Spatial data mining research is still in its early stage, and its great potential is yet to be fully realized by addressing new challenges, inventing novel methods, and developing successful applications. Following is a brief introduction to several selected major challenges facing spatial data mining research.

Pattern Complexity and Hypothesis Generation

Geographic phenomena by nature are often very complex, involving many known or unknown interrelated factors. The traditional hypothesis-testing approach has very limited capability because there can be numerous hypotheses for a simple geographic problem. A more viable direction that spatial data mining should take is to develop approaches that can search the data and suggest hypotheses.

Spatial Nonstationarity

To make the above problem even more challenging, patterns or relationships may change over a geographic space. For example, the causal factors for a cancer may vary regionally due to differences in living environment, economic status, and health policies.

Computational Efficiency

Because of the massive data volume, the large number of attributes, and the complexity of potential patterns, spatial data mining tasks are computationally demanding. For example, to detect clusters in a large set of spatiotemporal events (e.g., disease incidents) may take hours or even days of computations. This problem becomes much more severe if more factors are to be considered. Every spatial data mining method has to be computationally feasible to handle large amounts of data.

Visual Presentation and Understandability

The understandability of discovered patterns is very important for users to integrate the new information with existing knowledge for scientific inquiry and real-world decision making. Interactive visualization methods are critical to allow users to interactively explore and understand the patterns from different perspectives.

Practical Systems to Address Real-World Problems

One of the ultimate goals of spatial data mining is to help solve real-world problems such as those

related to pandemic control, emergency management, urban planning, business intelligence, global change, and weather forecasts, among many others. It is critical that spatial data mining research be able to produce effective approaches to benefit a broader community, in both scientific and public domains.

SPATIAL DATA MODELS

Spatial data models, or GIS data models, are the ways of representing spatial information in a geographic information system (GIS) database. Because the world is very complex, choices must be made on how to describe objects and phenomena for research and analysis. Typically, the selection of a particular scale of analysis is made, based

on information needs dictated by the task at hand, where the level of desired detail is portrayed in the model. Sometimes the choice of scale of analysis is constrained by access to data, particularly where satellite data may offer information only at a particular resolution. The categorization of the objects is also a critical decision: What information is to be included or excluded is carefully considered. From these choices, the spatial data collected are generalized (put into categories) and converted into abstract forms (a line represents a road, a point represents a city), and objects are simplified.

Through the choices of spatial representation, information becomes manageable, available for analysis, and straightforward to communicate and share. All spatial data models are spatially referenced: For objects described on Earth's surface, geographic coordinate systems serve as the reference. Spatial references can also be generated for other areas of focus: other planets, the human body, or the human brain, for example. In this entry, raster and vector, the most common spatial data models, are described first. The Triangulated Integrated Network (TIN) model, a variation on the vector data model, and the object data model, as a compilation of vector or raster data models, are also defined. Last, critiques of representation through spatial data models are summarized.

Raster Data Model

A *raster data model* is a two-by-two array, or grid, of spatial information. Analogous to the pixels that make up the image on a computer screen, or images taken with digital cameras, a raster model contains grid cells, spatially referenced and consisting of only one value in each cell. The value may represent temperature, elevation, or even population, estimated for each grid cell. A grid representation forms a surface of information. For raster data models, the choice of scale, categorization, and representation is made by the choice of resolution, or the size of the grid cell.

Vector Data Models

Vector data models use points, lines, and polygons to geometrically represent spatial entities. In contrast to the continuous array of cells in a raster model, spatial objects in vector data models

can be seen as discrete objects: points, representing cities, houses, or trees; lines, representing roads or rivers; and polygons, representing the boundaries of countries or states or the boundaries of buildings.

Spaghetti Data Structure

The simplest vector data model is the spaghetti data structure, where coordinates, or strings of coordinates, for points, lines, or polygons, are stored. The spaghetti structure does not store explicit information on how points, lines, or polygons are described in relation to one another. For example, data on intersections, proximity, and contiguity are not specifically stored.

Topological Data Structure

The topological data structure offers a more advanced data storage technique for vector data models. Information about topology, such as nodes and intersections, lines, and polygons, and about how the spatial entities are related to one another is stored in this structure. The advantage of the topological data structure, though it is more sophisticated, is that it shortens the time that it takes to conduct spatial queries or for users to ask questions about the spatial relationships that exist in the data.

Triangulated Integrated Network (TIN) Model

The Triangulated Integrated Network (TIN) model is a type of vector data model in which for a set of points, each point is connected with its neighbors in all directions by straight lines, forming a cover of triangles over a particular, referenced space. TIN models are commonly used to display differences in elevation. The advantage of the TIN model over the raster model for elevation is that data redundancy is reduced in places where there is not much difference in elevation change.

Object Data Model

In raster and vector data models, the spatial entities that are stored are not hierarchical. When dealing with complex, interrelated spatial information,

it makes sense to lump a series of entities into a larger object, or set. For example, roads, buildings, and important distribution sites may make up a city. With the object data model, multiple layers of entities are included in a more encompassing object. Components of objects may include different types of raster or vector entities: points, lines, or polygons. In some cases, the classification of entities as part of an object is intuitive; however, for other applications, enforcing one object data structure, with distinct and separate entities belonging only to particular objects, may not be the best choice.

Critiques of Spatial Data Models

Criticisms of the choices made regarding representation in a GIS are diverse, adding to an already healthy critical perspective of cartography. Boundary drawing is an exercise in power: power over nature and power over people. As in cartography, spatial data models in a GIS represent information that is necessarily imperfect: generalizing, simplifying, and exclusionary of certain sets of information. Reflecting less on the shortcomings and more on the potential in the burgeoning field of GIS, the way in which time is incorporated into spatial models has been a source of critique and an area of important development for the future of GIS.

SPATIAL DATA STRUCTURES

Spatial data structures describe the rules that are used to represent geographic data in geographic information systems (GIS). Geographic data include information about the location, size, and shape of objects or phenomena on or near the surface of Earth, as well as their nonspatial characteristics.

Geographic data in GIS are represented at several different levels of abstraction, each level depending on those beneath it:

Conceptual spatial data models describe how geographic objects (e.g., rivers) or phenomena are represented in GIS.

Logical spatial data models describe how geographic data are represented in a database management system (e.g., as database tables).

Spatial data structures describe the methods and formats for physical storage and processing of geographic information in GIS.

Spatial data structures are the core of a GIS and fundamentally affect its performance and capabilities. Thus, an understanding of spatial data structures is important in the study of geographic data management.

Data structures can be divided into two groups. *Vector* data structures represent geographic objects or phenomena as distinct geometries with specific characteristics and may also include topology. *Raster* data structures represent geographic objects or phenomena as a grid over

which a given characteristic varies continuously. Generally, raster data structures are suitable for continuously varying phenomena, such as temperature, while vector data structures are suitable for the representation of conceptually distinct objects, such as land ownership parcels.

Vector Data Structures: Geometry

Vector data structures explicitly store the geometries that represent geographic objects. They are referred to as *vector data structures* because they represent geometries using a series of points and lines (vectors). In vector data structures, geometries may have different dimensions (Figure 1):

A zero-dimensional (0D) geometry is a point. It is usually represented with x and y coordinates.

A 1D geometry is a line, arc, or string of line segments (sometimes called a *polyline*) connecting point geometries, sometimes requiring additional information about arc properties.

A 2D geometry is a polygon, defined by a sequence of 1D geometries with the same start and end point. Polygons may be simple or complex. Complex polygons may be aggregations of more than one polygon and may have holes, possibly with island geometries inside the holes.

A 3D geometry is a solid, defined by a collection of 2D geometries with a z coordinate (usually representing height relative to a reference point). The solid may also contain holes or be an aggregation of multiple solids.

Geometries may have attributes attached to them. For example, a land ownership parcel may be represented by a 2D geometry (polygon), with attributes for the name of the parcel owner and the land use controls that apply over it.

Vector Data Structures: Topology

Some spatial data structures represent topology as well as geometry. Topology describes how objects are connected to one another.

The topology of a set of objects can be represented by a graph of nodes and links.

Figure 1 Geometries

Source: Author.

Figure 2 Topology

Source: Author.

Formally, topology describes the set of relationships between objects that are not changed when object geometries are deformed in various ways (twisted, stretched, or resized). In topological spatial data structures, the connections between objects are stored in addition to their geometries, and thus, when there is a change in the geometry of one object, the geometry of a connected object

may also be affected. For example, in Figure 2a, although Points A and B coincide, when B is moved, A is not affected. In Figure 2b, Point A is stored as a node of both polygons, and there is no Point B. When Point A is moved, it affects the geometries of both polygons.

Raster Data Structures

Grid (or raster) data structures represent the world as a grid of cells that have a location and an attribute value or set of values for that cell. There are a number of different ways in which the grid may be physically represented within a GIS.

Most simply, a grid may be represented as a list of coordinates (cell row and column) and an attribute value or set of values. However, such an approach is not usually efficient for data retrieval because adjacent points in the world are not adjacent to each other in the representation and it does not support convenient aggregation of cells to allow a large area to be viewed efficiently. For this reason, hierarchical (or pyramidal if 3D) data structures have been developed that progressively divide the gridded region.

The quad-tree data structure (Figure 3a) is a hierarchical structure with a single cell representing the entire region at the root, which is then progressively subdivided into four blocks (typically northwest, northeast, southwest, and southeast). If a quad-tree block is filled with cells that have the same attribute value, that value is stored. Otherwise the subdivision process is repeated. Irregular quad-tree data structures (Figure 3b) may also be used. In this case, the area is still divided into four blocks successively, but the position of the boundaries between the blocks is determined by the contents of the area.

The r-tree (or rectangle-tree) is similar to the irregular quad-tree but with more flexibility. Any number of rectangles may be formed around features, objects, or clusters; areas that are empty may be ignored, and rectangles may overlap (Figure 3c).

Raster data structures are sometimes used to improve the efficiency of vector data retrieval by not only representing objects as geometries but also referencing the geometries against cells

Figure 3 Raster data structures

in a hierarchy. This approach allows geographically neighboring geometries to be found more efficiently.

SPATIAL DECISION SUPPORT SYSTEMS

Although the concept of spatial decision support systems (SDSS) has been around for approximately 40 years, it was not until the early 1990s that SDSS found a wider recognition in geography and geographic information science (GIScience). The development of SDSS has been associated with the need to expand geographic information system (GIS) capabilities for tackling complex spatial decision problems. Over the past two decades, the SDSS concept has evolved into a field of research, development, and practice that is made up of many different approaches and frameworks, among which are Collaborative SDSS (CSDSS), Group SDSS (GSDSS), Intelligent SDSS (ISDSS), Participatory GIS (PGIS), Public Participation GIS (PPGIS), Spatial Knowledge-Based Systems (SKBS), Spatial Multi-Agent Systems (SMAS), and Spatial Planning Support Systems (SPSS). A broader perspective suggests that all these spatial information systems have a

common aim: to improve the performance of decision makers, managers, and citizens when they confront spatial decision problems.

Defining SDSS

SDSS is an interactive, computer-based system designed to support a user or group of users in achieving higher effectiveness in decision making while solving a semistructured spatial decision problem. The essence of the SDSS concept is captured by the following three terms: (1) semistructured spatial problem, (2) effectiveness of decision making, and (3) decision support.

Any decision-making problem falls on a continuum that ranges from completely structured to unstructured decisions. Most real-life spatial decision problems can be found somewhere between these two extremes. Such decision problems are called *semistructured* (e.g., location-allocation problems, site search and selection problems, land use suitability evaluation, transportation problems, environmental impact assessment, plan/policy evaluation, etc.). The structured part of the semistructured problem may be amenable to automated solution by the use of a computer, while the unstructured aspects are tackled by decision makers. Although SDSS may increase the efficiency of the data-processing operations, the primary aim of the system is to improve the effectiveness of decision making by incorporating decision makers' knowledge and experience into computer-based decision-making procedures. Central to the concept of SDSS is the interaction of the user(s) with a computer-based system containing a set of tools for analyzing spatial and nonspatial data and for modeling spatial decision problems. SDSS integrates previously separate tool sets into a unified whole more valuable than the sum of the parts.

Components of SDSS

A number of frameworks for designing SDSS have been proposed in the past two decades or so. In general, the SDSS concept is based on the DDM (dialogue, data, and model) paradigm. The way the three components are integrated depends on the philosophy behind the design strategy (e.g., a system for supporting a single user vs. that for

Figure 1 The components of SDSS

Source: Author.

Note: DBMS = database management system; MBMS = model base management system; DGMS = dialogue generation and management system.

group decision making), the types of decision problems (e.g., operational vs. strategic decisions), and the models incorporated into the system (e.g., optimization vs. simulation models). Despite these differences, a well-designed SDSS should have a balance among three sets of capabilities in the areas of data, modeling, and dialogue (Figure 1).

The database management system (DBMS) contains the functions to manage the geographic database. It typically contains a set of tools that are available in full-fledged GIS, such as data acquisition, storage, retrieval, manipulation, queries, integration, and visualization, including techniques and methods for exploratory data analysis that provide decision makers with a better understanding of the decision situation. The model base management system (MBMS) contains the functions to manage the model base. It can include tools for decision analysis (e.g., generic optimization and simulation models as well as domain-specific models such as spatial interaction, spatial choice, location-allocation, resource allocation, land suitability, and hydrological models), statistics and forecasting (e.g., exploratory spatial data analysis, confirmatory spatial data analysis, spatial statistics, and time

series), modeling a decision maker's preferences (e.g., the hierarchical value structure of goals, evaluation criteria, objectives and attributes, multi-attribute value/utility, and consensus modeling techniques), and modeling uncertainty (e.g., "what-if" analyses).

The dialogue generation and management system (DGMS) manages the interface between the user and the computer system. It includes all the mechanisms by which commands, requests, and data are entered into the computer system as well as all the methods by which results and information are output by the system (e.g., cartographic displays, specialized graphics for depicting the results, and tabular reports). In addition, an SDSS may include some kind of artificial intelligence or Expert System (ES) capabilities to improve the accessibility, maintenance, and operation of its major components. The three components constitute the software portion of SDSS. In addition, the decision maker or user is considered to be a part of the system. The unique contributions of SDSS are derived from the interaction between computer and the user.

Changes in computer hardware and software technology over the past decade or so have fundamentally restructured the way in which decision makers, planners, analysts, and citizens interact with computer-based data and models for supporting decision-making processes. The Internet and the World Wide Web (WWW) have added a new dimension to the concept of SDSS. In particular, Web technologies provided new media for sharing information about decision support and a new means for delivering decision support capabilities. The main motivation for making SDSS available online is to stimulate and support group/participatory decision making. Web-based SDSS have reduced technological barriers and made it easier to provide decision-relevant information to users in geographically distributed locations. A Web-SDSS combines several different components, including HTML (Hypertext Markup Language) user interfaces, Internet interface programs, computational models, and geographic databases. It delivers decision support information or decision support tools to user(s) by means of a Web browser, such as Internet Explorer or Netscape Navigator.

Technologies for Developing SDSS

There are three sets of technologies for building an SDSS: (1) SDSS development tools, (2) SDSS generators, and (3) specific SDSS. The tools facilitate the development of specific SDSS, or they can be configured into an SDSS generator, which in turn can be used to build a variety of specific SDSS. Examples of development tools include procedural programming languages and code libraries (e.g., TransCAD—Caliper Script's macrolanguage), interapplication communication software (e.g., dynamic data exchange [DDE]), application-programming interfaces (e.g., TransCAD's API), applets (e.g., GISApplet), visual interfaces, graphics, and color subroutines (e.g., graphical user interfaces, or GUI).

The SDSS generator is a package of related hardware and software that provides a set of capabilities to quickly and easily build a specific SDSS. GIS (e.g., ArcGIS, MapInfo, TransCAD), database packages (e.g., dBase, Oracle Spatial, ArcSDE), decision analysis and optimization software (e.g., LINDO, EXPERT CHOICE), statistical and geostatistical software (e.g., S-PLUS, SPSS), and simulation (e.g., @RISK) can be used as SDSS generators. The specific SDSS is a system devoted to the analysis of a particular set of decision problems. It is the system that actually supports the decision makers in tackling particular spatial decision problems (e.g., CommunityViz, IDRISI).

Examples of SDSS

Theoretically, it is possible to develop specific SDSS in any area of application involving analysis of spatial data for tackling decision problems. Indeed, one of the most remarkable features of SDSS development is the wide range of decision and management situations in which they have been applied. SDSS capabilities are readily available in some GIS. IDRISI's Decision Support and Integrated Land and Water Information System (ILWIS), with its Spatial Multiple Criteria Evaluation feature, provides a good example of a system that has a wide range of GIS capacities, including decision support. IDRISI has been developed in the Clark Labs for Cartographic

Technology and Geographic Analysis at Clark University. It includes a suite of tools for multicriteria decision support that has been applied to support land use planning, risks and vulnerability assessment, sustainable forest management, hazardous material transportation planning, and emergency planning. ILWIS is a GIS and remote sensing software, developed by the International Institute for Geo-Information Science and Earth Observation (Enschede, the Netherlands). Like IDRISI, ILWIS includes a multicriteria decision support module that has been used for land use suitability analyses and water management. CommonGIS (developed by the Spatial Decision Support [SPADE] research team at Fraunhofer AIS, Germany) is an example of a Web-based GIS. It has a suite of visual and computational decision support tools that can be used for tackling spatial decision problems.

A large number of SDSS have been developed using a GIS as the SDSS generator. In particular, the products of the Environmental Systems Research Institute, such as ArcInfo, ArcView, and ArcGIS, have often been used as platforms for developing specific SDSS. For example, CommunityViz (a product of Placeways LLC) is a group of extensions to ArcGIS for urban planning, land use planning, and resource management applications. Spatial Group Choice, developed by a research team at the University of Idaho and the University of Washington, is an ArcView-based spatial decision support system that has been successfully used for habitat site selection, health care resource allocation, and railway transportation planning.

Many government agencies have developed SDSS to support their activities in the area of land use, transportation, and environmental planning and management. For example, the Spatially Explicit Decision Support System (SEDSS) for ecological risk assessment and restoration of the Everglades has been developed by the U.S. Geological Survey. RAISON (Regional Analysis by Intelligent Systems ON microcomputers) is an SDSS developed by Environment Canada. The Australian government, acting through the Bureau of Rural Sciences, has developed the Multi-Criteria Analysis Shell for Spatial Decision Support (MCAS-S) to tackle land use and natural resource management problems.

TRAILMAN (Transportation and Inland Logistics Manager) is an SDSS developed for the U.S. Agency for International Development to assist in distribution of food in Africa.

Criticisms of SDSS

The concept of SDSS has been criticized on several grounds. Some critics point out that SDSS practice tends to place too much emphasis on the use of GIS as an SDSS generator and that, therefore, it does not adequately address the issues of system integration, interoperability, user information needs, and the role of context in supporting spatial decision processes. There has been a tendency to adapt the decision-making processes to the existing geographic information technologies rather than to organize the SDSS research and to develop SDSS in the context of the decision-making processes themselves. Neglecting information needs and the socio-organizational contexts of decision processes impedes the widespread use of SDSS. It also diminishes the role of SDSS as a mainstream GIScience methodology. To this end, research addressing GIS from social science/participatory perspectives has contributed to the understanding of the dynamics of spatial decision processes and their socio-organizational contexts. This broadening of the traditional technical base of GIS usage has been supplemented by advances in the area of geocomputation, geovisualization, semantic Web methodologies, and interoperable Web services. These new developments in GIScience have the greatest potential to stimulate future progress in SDSS.

SPATIAL ECONOMETRICS

Quantitative geographers, as well as other social scientists, use the methodological techniques of spatial econometrics to analyze data in ways that help understand how humans are interrelated with one another across different geographic areas. More specifically, researchers use spatial econometric techniques to build regression models that attempt to mathematically represent the effects of human interdependence when explaining the factors leading to the geographic distribution of a variable. Spatial econometric techniques have been applied by researchers from a wide variety of fields, such as criminology, archaeology, regional economics, election analysis, international political conflict, and real estate analysis. Common to all these fields is the use of observational data that can be mapped (or geographically

referenced) to infer interesting spatial (or geographic) associations.

Strongly associated with the fields of regional science and quantitative geography, spatial econometrics emerged in the 1970s to deal with the problems social scientists were having in estimating regression models using cross-sectional data in the presence of spatial autocorrelation. The techniques developed out of a concern that it was unrealistic to accept the spatial independence assumption of standard econometric inference, which posits that the values at any one location are unrelated to those at other nearby locations. Like time-series methods, which account for how a data-generating process may be characterized by temporal dependence across lagged time periods, spatial econometric methods were developed to account for spatial dependence across geographically lagged locations, those locations defined as being synchronically within close proximity of one another. A feature distinguishing spatial analysis from time-series analysis is that the causal associations are not unidirectional but are multidirectional.

From a methodological perspective, spatial econometrics comprises a set of techniques to incorporate spatial dependence and heterogeneity into a regression model. Luc Anselin has described the techniques of spatial econometrics as falling into four broad areas: (1) specification of how to represent different forms of spatial dependence and spatial heterogeneity in a regression model, (2) estimation of model parameters, (3) model specification tests and diagnostics of the potential presence of dependence within the data-generating process, and (4) model prediction. A key requirement of the estimation techniques of spatial econometrics is that the data be based on observations that have been geographically referenced at the time they were recorded, often as the centroids of a lattice of regions.

Functional Forms of Interdependence

The field of spatial econometrics has contributed a framework that allows social scientists a rigorous way to communicate their notions of the observed complexities of how humans in different geographic areas may be associated with one another. Spatial econometrics can be used to assess how the value of a variable in one location

depends on attributes in other locations. For example, consider the relationship between government spending and income over a geographical system, $A = \{1, \dots, n\}$.

The functional dependencies between some region i and the other L regions in the geographical system can take a variety of forms that can guide the design of a spatial regression model and, more generally, guide an understanding of differentiating between types of interdependence. Each form of functional dependency below, when estimated as a regression model, results in quantitatively different degrees of interdependence between locations, or, more technically, different spatial covariance structures.

Aspatial Process

An aspatial approach is as follows:

$$\text{Income}[i] = f(\text{Spending}[i]).$$

In this case, we model income (**Income**) in a region as being only a function of government spending (**Spending**) in the same region. If we are interested in understanding the causal relationship between government spending in other regions in spatial proximity to *region i* and income in *region i*, this aspatial model may unrealistically ignore economic externalities. As an example of the potential externalities being ignored, income benefits to *region i* can occur through government spending in neighboring regions, say from new roads or tourist facilities.

Conditional Autoregressive Process

A conditional autoregressive process can be represented as follows:

$$\text{Income}[i] = f(\text{Spending}[i], \text{Spending}[L]).$$

The dependent variable, **Income**[i], depends on both spending region i , **Spending**[i], and spending in other regions, **Spending**[L]. Spatial market externalities can be represented with this functional form. For example, a government investment by one community that helps in attracting tourists to the area will most likely also benefit the tourist industries of neighboring communities.

Spatial Lag Process

A spatial lag process can be represented as follows:

$$\text{Income}[i] = f(\text{Spending}[i], \text{Income}[L]).$$

In this case, income in one region is affected not only by government spending in the same region but also by income in other regions. An example of this process is economic growth spillovers due to interindustry linkages among associated regions.

Spatial Error Process

A spatial error process can be represented as follows:

$$\text{Income}[i] = f(\text{Spending}[i], e[i], e[L]),$$

where e denotes an error or random disturbance, capturing the effects on income that the researcher assumes cannot be empirically accounted for in a systematic way. Here, a region's income depends on the random disturbance in both that region and other regions. As an example, if we assume that e captures random disturbances to an economy such as closed roads from bad weather, then it is reasonable to infer that the shocks to one region's economy may also spill over to affect the economy of surrounding regions.

Space-Time Lag Process

Finally, a space-time lag process can be represented as follows:

$$\text{Income}[i, t] = f(\text{Spending}[L, t - 1]).$$

The term t denotes a time period, and $t - 1$ denotes the previous time period. Here, dependence occurs across both space and time, as the value of **Income** in a region i at time t now depends on spending in other regions from the previous time period.

A common methodological challenge in the specification of spatial structure in a regression is in defining a function of proximity that quantifies the variation in the degrees of influence that regions (or more generally, any set of spatially referenced objects) have on one another. The

problem of what measure to choose to approximate a theoretical concept of spatial proximity in model specification can be considered both positively, as a creative challenge, and negatively, as an unwelcome ambiguous choice. The proximity function needs to be both theoretically relevant to the study at hand and empirically feasible given the available data. For instance, the spatial proximity of two economic regions might be measured in many ways, such as the Euclidean distance between the centroids of two polygonal regional shapes, the length of their shared borders, the time duration of travel between the largest cities of two regions in an automobile, the magnitude of the commuter flows between the regions, the socioeconomic similarity of the regions, or the value of the annual commodity flows between the two regions. Hypothetically, if the objective of the modeling effort is to understand what variables are important for predicting some diffusion process, say political conflict, then using the length of the shared border of two regions may be a relevant way to measure proximity. On the other hand, if we are concerned with predicting the influence of economic growth of one region based on development in neighboring regions, then using a measure of commodity or commuter flows may be a more relevant way to weight the relative importance of the different regions. Such information relating to the spatial structure of interdependence can be represented with a spatial weights matrix, $\mathbf{W}$, whose elements, w_{ij} , can be defined using information on some prior notion of spatial proximity or association between the objects of analysis at locations i and j .

Using this spatial weights matrix, an equation can be written that describes a conditional autoregressive form of the relationship between income and government spending for a multiregional system, which can be estimated using regression:

$$\text{Income}[i] = (b_0 + b_1)\text{Spending}[i] + p\mathbf{w}_i\text{SPENDING} + e[i],$$

with $\mathbf{w}_i$ a row vector of the spatial weights matrix, $\mathbf{W}$, denoting region i 's spatial proximity to the other regions, L , in the geographical system. **SPENDING** is a one-column vector of regional spending variables that when multiplied by $\mathbf{w}_i$ gives a weighted average variable of spending in other

regions. p denotes the estimated parameter that captures the direct effect of this spatial component, $\mathbf{w}_i\text{SPENDING}$, the effect of regional spending on income within each region. The parameters b_0 and b_1 are also estimated in the regression.

Recent Developments

Spatial econometricians are currently extending the field by simultaneously accounting for both spatial and temporal dependence structures, applying spatial probit models, and using Bayesian estimation methods.

In addition, accessibility to spatial econometric techniques has recently been widened by the development of new software. Examples are Roger Bivand's Spdep module for the R open-source statistical package, Luc Anselin's Geoda software, Sergio Rey's open-source STARS package, and Jim LeSage's Spatial econometric toolbox for Matlab. The development of open-source computational tools for the application of spatial econometric methods can be thought of as a way to increase the transparency of such modeling choices for the scientific community.

In recent years, the application of spatial econometric methods has increased. This trend may be attributable to various intellectual and practical factors. There may be a more widespread understanding of the mathematical representations of spatial structure. There may be an increased wave of curiosity, with a broader basis than spatial econometrics, to explore how conventional statistical approaches that ignore human interdependence may be biasing our inferences on aggregate human behavior. In a practical sense, the growing popularity of GIS among social scientists may have also eased the challenge of defining and testing various types of spatial proximity functions, piquing the interest of researchers to explore how spatial effects may play a role in obtaining cross-sectional regression results at a minimal cost.

Criticisms of Spatial Econometrics

In human geography, spatial econometrics can be thought of as being located on the far edge of the quantitative side in the quantitative versus qualitative methodological divide. Spatial econometrics' language of rigorous, formal mathematical logic

may be thought of as a deterrent to the understanding of the results of its research applications by those outside the field. Since a significant portion of the substantive problems that spatial econometrics is applied to deals with social welfare issues such as regional economic growth, urban crime patterns, and international conflict, its models have been criticized as being overly complex to interpret by other geographers. At the same time, such a modeling approach can also be thought of as a new way to complement, rather than compete with, more intuitive approaches, such as visually observing patterns in choropleth maps, which geographers have traditionally used to infer spatial associations and to describe new models.

In a sense, the rejection of the spatial independence assumption, a cornerstone of the field of spatial econometrics, comes at the cost of increased analytical complexity. In another sense, the field of spatial econometrics can be credited with advancing the frontiers of how applied researchers confront empirical problems, attempting new and innovative ways to link regression modeling with theoretical knowledge of spatial processes to model complexities of the human landscape that may have previously been ignored or considered intractable.

SPATIAL FIX

The term *spatial fix* is embedded in Marxian thinking, which emerged in geography in the early 1970s. It is closely associated with the pioneering work of David Harvey on the historical geography of industrial capitalism. The spatial fix depicts the inherent contradictory nature of capitalism, which has explicit geographical dimensions. First, the spatial fix reflects the intrinsic need of capital to spread out over space in order to overcome its inherent crises of overaccumulation; second, it means securing and deepening a presence in specific locations as a result of built-up investments over time. It has become an important notion within Marxist-influenced human geography and has been applied in a variety of different contexts.

The Spreading Out of Capital

The most acute, persistent problem in industrial capitalism, a falling long-term rate of profit, is linked to overaccumulation crises, a condition in which too much capital is produced relative to opportunities for profitable use for it. In essence, Marxist economics, centered on the labor theory of value, holds that capitalism has a built-in tendency

to produce too much, causing declines in prices and thus profits. In this context, the *spatial fix* has a metaphorical meaning. The term describes capitalism's voracious drive to resolve its inner crisis tendencies through geographical expansion (i.e., finding new markets) and subsequent geographical restructuring. In some sense, it means changing the spatial distribution of factories, investments, and employment by spatial mobility. Spreading out is conceived as a useful mechanism to lessen and delay the negative impacts of economic restructuring by absorbing excess capital.

Integrating additional territories into the circuits of capitalism plays a role in alleviating difficulties. Several spatial scales exist over which capital is spread. At the metropolitan level, suburbanization has been the archetypal spatial fix, as low-cost mortgages and highway systems have propelled the demand for cars and numerous appliances. This process resulted in an increasing tendency for firms and people to move away from declining central cities to emerging new communities. On the global scale, imperialism and colonialism were potential solutions to the internal contradiction of capitalism by spreading out to fresh spaces for accumulation. Recent improvements in communications and transportation make investment flows speedier and cheaper, and globalization is the contemporary version of capitalism's search for a spatial fix to its crisis tendencies. A crisis of overaccumulation in a particular region may lead to the export of capital and labor surpluses to new territories to start up new production there, generating new rounds of uneven development. Surpluses of capital and shortages of labor are swept either by the movement of capital to areas of labor surpluses or by the import of cheap labor into centers of capitalist development. A widespread strategy of many multinational firms has been to relocate factories and production to sites with lower production costs in developing or less developed countries.

The spatial fix was the geographical solution for the inherent problems of capitalism in a loosely connected world. In the long run, however, as global interconnectedness becomes more prevalent, overaccumulation crises are more difficult to postpone on the global scale, so they intensify. By employing the strategy of geographical expansion, capitalism, according to David

Harvey (1985), buys "time for itself out of the space it conquers" (p. 60); nonetheless, this annihilation of space with time cannot go on indefinitely, nor can the spread of conditions for crisis formation over ever-wider spheres be avoided.

Grounded Capital and the Built Environment

Despite a relentless desire to move around the globe, capital investment tends to flow into well-established sites of capital accumulation. The production of urban space and built environment is pursued through switching capital from direct production (primary circuit) to urban infrastructure and technology and human capital (secondary and tertiary circuits). Taking this view, Harvey suggested that in the long run, in the absence of profitable investments in the primary circuit of capital accumulation, capital will flow into the secondary circuit, where it is deployed in the production of the built environment.

Mobility in itself is not sufficient for facilitating capital movement, so ever-growing expansion often depends on the advantages of geographical stability. To function effectively, immovable structures are necessary for the reduction of the cost of moving across space. This type of spatial fix is achieved through securing investment in space in the form of office buildings and communication networks, for example, creating a new environment suitable for capital accumulation. Each form of geographical mobility of capital requires fixed and secure spatial infrastructures. Therefore, a certain portion of capital has to be fixed in place (land and other built forms) for a relatively long period of time; existing urban centers and production capacities serve as the basis for new investments. Eventually, space built for a certain period of time has to be destroyed to make way for a new spatial fix at a later point in time. Profound economic restructuring such as the transition from mass production systems (Fordism) to flexible production (post-Fordism) may result in the obsolescence of the built environment in older industrial cities, forcing capital to seek alternative spatial outlets. In other cases, continuous investment of capital in the built environment strengthens established nodes, which have enjoyed decades of investment in urban infrastructure of all kinds. Despite suburbanization, the central

business district (CBD) is still an important node in the metropolitan area, and this is partially attributed to the entrenched qualities of its built environment. On the global scale, world, or global, cities such as London, New York, Tokyo, and Paris, with their built corporate complexes, stock exchanges, and highly developed telecommunication and transportation networks, are fixed at the top of the global urban hierarchy.

some respects relevant to the human sciences. Inequality is most commonly explained with reference to genetic predisposition, individual action, and social forces, or some combination of the three that leads to disparities between two or more unequal individuals or groups. The means of quantifying inequality are often quite sophisticated and are consistently used to analyze the development of a given group relative to its own past and relative to the situation of others within a specific time frame.

Spatial inequality is a particular form of inequality. Inequality is more generally the study of “who gets what and why.” Adding a spatial characteristic means integrating an element of “where,” enriching the concept by seeking to explain how social, political, economic, and cultural discrepancies relate not only to ideas, structure, and agency but also to the specific attributes of space in the material world. Spatial inequality is a concept that seeks to explain and illustrate discrepancies among populations regarding outcomes, conditions, and/or opportunities across different spaces and spatial scales. It shows inequality in terms of different spatially located demographics and their relationship to a given set of variables.

Spatial inequality occurs for a number of reasons, including the formation and operation of class; racism and/or prejudice toward cultural, ethnic, or minority groups; and other discriminative views and practices (e.g., based on gender, religion, age, or sexuality). Equally important, however, is a clustering among socioeconomic lines, which is a general feature of spatial inequality. Figure 1 shows the level of intra- and intercountry economic disparity among four countries. Economic disparities are a useful and common way of measuring inequality. The graphic shows that while Brazil's richest people are as rich as those of France, its poorest are poorer than the poorest in rural Indonesia. Clearly, this kind of analysis is useful in understanding the massive discrepancies on two different spatial scales, in this case national and global.

Spatial inequality can also be considered in terms of the unequal distribution in goods or services depending on an area or location. Inequality in services, for instance, means that the provision of medical aid or education will differ among spaces. Figure 2 shows the results of a study that found a correlation between nonattendance rates

SPATIAL INEQUALITY

The study of inequality seeks to analyze the causes, contexts, conditions, and outcomes of disparities between two or more groups over a given number of variables. It differs from a study of difference insofar as the former assumes a quantifiable progression from worse off to better off in

Figure 1 World income distribution by percentile across four countries, 2005

Source: Malanovic, B. (2006). Global income inequality: What it is and why it matters. *World Economics*, 7(1), 19.

and school densities in counties in Gansu province, China. The map shows that counties with a relatively weak density of lower-secondary schools have a higher girls' nonschooling rate than counties with high densities of lower-secondary schools. This study demonstrates that the longer the distance from schools, the higher the opportunity cost of acquiring education and the greater the gender disparities in the school attendance rate.

Spatially, inequality can be examined globally, regionally, nationally, and locally. It can be measured between the global North and the global South, between Asia and North America, between

the United States and China, or between New York and Shanghai. Within countries, spatial inequality studies can evaluate the difference in outcome, condition, and/or opportunity on an interurban scale (e.g., New York vs. San Francisco), an intra-urban scale (e.g., the Lower East Side vs. Harlem), an urban-rural scale (e.g., the Atlantic Northeast vs. the Midwest), and a rural-rural scale (e.g., Appalachia vs. the Midwest). Many other scales are also open to comparison in studies of spatial inequality. Figure 3 shows an example of intraprovincial spatial inequality. We can observe the disparity between per capita

income in Kolkata and in other districts of West Bengal in 2004–2005. No other district in the province had a per capita income that was even half that of Kolkata, not even those that are contiguous to or located near the capital. More than half the districts had per capita incomes of around one third (or less) that of West Bengal's capital. It should also be noted that for almost every district, the per capita income gap with respect to Kolkata has actually widened since 1999–2000, indicating that the recent pattern of economic growth has accentuated spatial inequalities within the state.

Studies of spatial inequality are well suited to representing the dynamic process of change across different spatial scales. They can offer a more nuanced perspective of migratory patterns, remittances, and the impact of global and national flows of capital, goods, and services on local, regional, and national demographics. Spatial inequality is a

useful focus for mapping migrants or the dynamics of slum settlements as they relate to increasing urbanization in the global South and the processes of change of large metropolitan cities such as gentrification and redevelopment. Figure 4 demonstrates the relationship between income discrepancies and slum population in a number of countries in the global South. As an example of spatial inequality, it is successful in demonstrating the linkages between national and local spatial scales through a common pattern of economic outcomes. For instance, Sierra Leone has both the highest income ratio and the highest population of slum dwellers as a proportion of its urban population. The correlation does not hold across all countries, however, as Honduras has high income inequality but a low percentage of slum dwellers.

Studies of the spatial differentiation of outcomes, conditions, and opportunities between

different demographics are applicable to every field of study in the human sciences. The use of such a method of study arose out of a need to address the spatial dynamics of change that occur in tandem with economic and political changes and shifts in the cultural and social outlook among populations. Recent spatial inequality research has sought to study spatial inequality for manufacturing wages in five countries in Africa and the process of peri-urbanization in Albania, among others. Table 1 shows some unmet basic needs for urban and rural Albania as well as for the capital, Tirana, demonstrating a clear urban bias, which becomes more pronounced for the capital. Tirana clearly acts as a hub of social and economic activity, to which the provision of social goods is a response.

Studies of spatial inequality have developed rigorous methodologies for mapping the discrepancies of different variables across demographics in different spaces and at differing spatial scales. Methodologically, they are strongly related to quantitative analysis, which has been aided by the development of geographic information systems (GIS).

The study of spatial inequality can be constrained by the ability of the researcher to amass data relevant to both a given spatial scale and the variable(s) being studied. For example, large-scale surveys, particularly in poor countries, are not always a reliable source of information. Moreover, the breadth of studies of spatial inequality risks revolving primarily around studies that relate to economic well-being, when inequality

may reflect an underlying bias that resides more in geographical, social, or cultural predilections than in overt political or economic exclusion or weakness. Thus, qualitative studies of spatial inequality should be used to place the results gleaned from research into a larger context of human activity and geographic space using various theoretical models.

SPATIAL INTERACTION MODELS

The interest in spatial interaction models is motivated by the need to understand and explain flows of people, commodities, capital, information, or even knowledge across geographic space. By adopting a spatial interaction modeling perspective, attention is focused on interaction patterns at the aggregate rather than the individual level. The basis of modeling is the use of a discrete zone system. Discrete zone systems can obviously take many different forms, in relation to both the level of resolution and the shape of the zones. But quite often, one is forced to use administratively defined regions, such as statistical enumeration areas or the wards of a city. The level of resolution used in the spatial interaction model is in part determined by the discrete zone system.

Spatial interaction models recognize three types of factors to explain the mean interaction frequencies between the origin and destination zones of interaction:

1. Origin-destination variables that characterize the way in which spatial separation of origins from destinations constrains or impedes the interaction
2. (Origin-specific) attributes that characterize the ability of the origins to produce or generate flows
3. (Destination-specific) attributes that represent the attractiveness of destinations

Suppose we have a spatial system consisting of n zones. Let i denote the origin ($i = 1, \dots, n$) and j the destination zone ($j = 1, \dots, n$) of interaction. Then, spatial interaction models may be described as those models that assert a multiplicative relationship between mean interaction frequencies and the effects of origin, destination, and separation variables. The basic form of the spatial interaction model may be expressed—mathematically—as

$$T_{ij} = CA(i)B(j)S(d_{ij}), \quad i, j = 1, \dots, n, \quad (1)$$

where T_{ij} represents the mean interaction frequency from i to j ; C denotes a constant term; $A(\cdot)$ and $B(\cdot)$ are some origin and destination weight functions that involve origin and destination attributes, respectively; $S(\cdot)$ is some distance deterrence function that is hypothesized to summarize all effects of space on interactions; and d_{ij} denotes the spatial separation from i to j . At relatively large scales of geographical inquiry (such as the country scale), this might simply be the straight line (Euclidean) distance separating an origin from a destination. In other cases (such as the regional or urban scales), it might be the travel time, cost of travel, or any other sensible measure of the separation of origins and destinations.

The exact functional form of the three terms on the right-hand side of Equation 1 is subject to varying degrees of conjecture. There is wide agreement that the origin and destination weight functions are generally best given by the power functions

$$A(i) = (a_i)^\alpha \quad (2a)$$

and

$$B(j) = (b_j)^\beta, \quad (2b)$$

where a_i represents an appropriate variable measuring the propulsiveness of i and b_j an appropriate variable measuring the attractiveness of j in a specific spatial interaction context. The exponents α and β are parameters to be estimated.

The distance deterrence function constitutes the very core of spatial interaction models. Hence, a number of alternative specifications of $S(\cdot)$ have been proposed in the literature. But the negative

exponential function is a popular choice (with theoretical relevance from a behavioral viewpoint)

$$S(d_{ij}) = \exp(-\theta d_{ij}), \quad (3)$$

where θ may be interpreted as a distance sensitivity parameter that has to be estimated. As d_{ij} increases, $\exp(-\theta d_{ij})$ decreases. It decreases faster the larger the value of θ becomes.

From a practical viewpoint, it may be convenient to extend the exponential specification (Equation 3) to the multivariate case

$$S(d_{ij}) = \exp \left[\sum_{k=1}^K \theta_k d_{ij}^{(k)} \right], \quad (4)$$

which provides a flexible representational framework for analyzing different types of spatial separation, such as the effects of geographical distance, border, and cultural and language barriers. $d_{ij} = (d_{ij}^{(k)} : k \in K)$ and $\theta = (\theta_k : k \in K)$, where K denotes the number of separation measures. This multivariate exponential specification of the spatial deterrence function leads to the well-known class of exponential spatial interaction models

$$T_{ij} = C(a_i)^\alpha (b_j)^\beta \exp \left[- \sum_{k=1}^K \theta_k d_{ij}^{(k)} \right]. \quad (5)$$

Fitting models of this type to observed data is a question of estimating the unknown parameters α , β , θ_k and the constant term. It is tempting to take logarithms of both sides of Equation 5 and write it in a linear form as

$$\log T_{ij} = \log C + \alpha \log a_i + \beta \log b_j - \sum_{k=1}^K \theta_k d_{ij}^{(k)} \quad (6)$$

and then proceed to estimate parameters by using ordinary least squares regression of the observation, say t_{ij} , on a_i , b_j , and $d_{ij}^{(k)}$ for $k = 1, \dots, K$. But such an approach suffers from two major shortcomings.

First, it cannot be guaranteed that the predicted flows when summed by rows or columns will necessarily have the property to match the observed totals leaving the origins i ($i = 1, \dots, n$) or terminating at destinations j ($j = 1, \dots, n$) in the given spatial interaction system. If the outflow totals for each origin zone and/or the inflow totals into

each destination zone are known a priori, then the log-linear regression model (Equation 6) would need to be modified to incorporate the explicitly required constraints to match the exact totals. Imposing origin and/or destination constraints leads to production-constrained, attraction-constrained, and production/attraction-constrained spatial interaction models that may be convincingly justified using entropy-maximizing methods.

Second, estimating the model parameters by ordinary least squares regression would be only justified statistically if the flows T_{ij} were independent and log-normally distributed about their mean value with a constant variance. This assumption is apparently not valid, since flows are discrete counts whose variance is very likely to be proportional to their mean value. Thus, ordinary least squares regression estimates and their standard errors can be seriously distorted.

For these reasons, spatial interaction models should not be estimated by an unconstrained log-linear regression. Maximum likelihood parameter estimation under more realistic distributional assumptions is generally more suitable. The most common assumption is that the T_{ij} values follow independent Poisson distributions with expected values $E[T_{ij}] = CA(i)B(j)S(d_{ij})$. This assumption is also open to question, since flows are not strictly independent. Moreover, a Poisson distribution may not adequately reflect the degree of variation present in the given data set if, for example, in migration contexts, individuals tend to flow in groups rather than as individuals. Nevertheless, this assumption is generally considered to lead to reasonable parameter estimates (see Bailey & Gatrell, 1995, for more details).

Neural spatial interaction models represent the most recent innovation in the design of spatial interaction models. These models are receiving increasing attention in recent years because of their powerful universal approximation properties. The interested reader may consult Fischer and Reismann (2002), who discuss some major principles of a methodology that enables one to efficiently use neurocomputing techniques for modeling complex spatial interaction phenomena at any level of spatial resolution.

SPATIAL INTERPOLATION

Geographic information is collected to support scientific investigations and decision making in a wide variety of domains (e.g., ecology, environmental engineering and science, geography, geosciences, public health, and social sciences). Spatial interpolation, one of the most widely used spatial analysis methods, is often integrated within geographic information systems (GIS) to estimate unknown or unavailable information associated with locations of interest based on collected information. Spatial interpolation is described in most of the textbooks in GIS and spatial analysis. This entry provides a concise but comprehensive review of spatial interpolation methods with a focus on the computation of spatial interpolation.

Taxonomy

Spatial interpolation methods can be developed based on different assumptions, purposes, and

evaluations. These methods exploit Tobler's (1970) famous first law of geography: "Everything is related to everything else, but near things are more related than distant things" (p. 236). For example, local perspectives for interpolation often assume positive spatial autocorrelation, while global perspectives tend to find trend surfaces across the entire space being considered. Spatial interpolation also depends on the type of spatial entities (e.g., point and area) where measurements are made and estimations drawn. The difference between point and area entities contributes to the distinction between point-based and areal interpolation methods, developed for the purposes of different applications such as point-based temperature surface interpolation and the areal interpolation of population characteristics between different areal units (e.g., census tracts and blocks). Consistent with the general concept of interpolation, spatial interpolation is often assessed by whether an interpolated value matches a given sample (i.e., exact interpolation) or not (i.e., approximate interpolation).

Another way to classify spatial interpolation focuses on whether statistical properties are addressed. Deterministic interpolation (e.g., inverse distance weighted, referred to as IDW) does not incorporate consideration of the randomness and probability of spatial variables, while geostatistical interpolation (e.g., kriging) does. A particular spatial interpolation method may take deterministic or geostatistical approaches, hold local or global perspectives, tailor to be point based or areal, and produce approximate or exact outcome. These various aspects of taxonomy are often combined with each other and integrated with additional dimensions (e.g., temporal) based on application requirements and the constraints of computational tractability, leading to many kinds of spatial interpolation techniques and algorithms.

Computation

Computation of spatial interpolation is often intensive for sizable data sets, and thus, high-performance computing environments based on parallel and distributed processing have been employed to enable large-scale interpolation. For example, the IDW interpolation has been extensively studied to improve the performance of computation required to find the nearest neighbors on which calculations

are based. To find nearest neighbors is a well-defined computation problem—formally called *k*-nearest neighbor search—that is notoriously computationally intensive. Various IDW interpolation algorithms have been developed based on parallel and distributed computing architectures. Most of these algorithms exploit the spatial distribution characteristics of data sets to resolve the computational intensity of *k*-nearest neighbor search.

Another example of computationally intensive spatial interpolation is Bayesian kriging, which provides realistic estimation of interpolation error and is able to combine information from disparate sources. However, Bayesian kriging based on Markov chain Monte Carlo (MCMC) methods poses even more significant computational challenges than classical kriging. Both require linear algebra operations that are computationally intensive when the number of measurement locations is large. Because an MCMC sampler typically must be run for thousands of iterations, each requiring numerous operations, the run time for sequential Bayesian kriging algorithms quickly becomes unacceptable. Even with parallel MCMC algorithms running on single high-performance computers, run times may be in the range of several hours, especially for vast geographic data sets. Therefore, the emerging cyberinfrastructure provides an ideal platform to develop parallel MCMC algorithms for Bayesian kriging by taking advantage of dynamically configurable computer resources.

As the size of individual spatial data sets continues to increase, driven by application requirements and enabled by advanced geospatial technologies, the computation of spatial interpolation must be scalable to the sheer size of data sets through the efficient use of cyberinfrastructure. A theoretical approach—spatial computational domain—has been demonstrated to capture the spatial characteristics of an IDW method to satisfy computational requirements for interpolating sizable data sets based on the efficient use of cyberinfrastructure, while the design of this approach is extensible enough to resolve the computational intensity of other spatial interpolation methods.

SPATIALIZATION

Spatialization is the transformation of high-dimensional data into lower-dimensional geometric representations on the basis of computational methods and spatial metaphors. Its aim is to enable people to discover patterns and relationships within complex, n -dimensional data while leveraging existing perceptual and cognitive abilities. Spatialization can be applied to various types of data, from numerical attributes to text documents and imagery.

Spatial Metaphors

The main cognitive underpinning of spatialization lies in the extensive use of spatial metaphors, including cartographic and geographic metaphors, such as *map*, *scale*, *distance*, *region*, and so forth, which enable users to “see” n -dimensional relationships within a low-dimensional visualization. Empirical support for this approach is growing. For example, human subject studies have shown that people expect that distances between point symbols representing text documents correspond to the documents’ relative similarity. Such distance-similarity relationships can further be manipulated through the introduction of network links (likened to cities connected by a road network) and through variations in symbology (e.g., the creation of visual groupings based on common symbols). In other words, the combination of the low-dimensional geometry with the set of traditional visual transformations developed largely within cartography can powerfully support the communication and discovery of complex, high-dimensional relationships.

Types of Spatialization Applications and Data

Spatialization can be applied to many different data types in many different application domains. Intelligence and law enforcement agencies need to sift through mountains of text, audio, and video content to extract useful nuggets of information. Research-funding agencies receive thousands of grant applications every year, from which they would like to identify emerging research trends and promising new approaches. In an increasingly

interdisciplinary research arena, both novices and experts find it difficult to stay abreast of the latest advances and are looking for condensed overviews of research results. Environmental scientists are increasingly receiving continuous streams of data from sensor networks, often involving dozens of attributes. Stock market analysts stand to gain from observing unusual market movements, including the relationships between different segments of the economy. Meanwhile, even average computer users find it difficult to keep track of the contents of hard drives containing hundreds of gigabytes of data.

Spatialization has been proposed as one possible approach for all these scenarios. However, we are faced with extremely different data sources, and the methods for turning them into visual form vary accordingly. One way of distinguishing different data sources is according to the degree to which they already consist of a coherent, consistent structure that is supportive of further processing.

Some data are highly structured, with a clear distinction between different elements and consistent attribution, and stored in standard database tables. Population census attributes are a good example, as they are attached to distinct geographic features and have a consistent attribute structure (at least for a given census year). Environmental attributes collected by sensor networks are another example of well-structured data.

On the other hand, there are data exhibiting much less existing structure. Most text, audio, or image contents are good examples. The middle ground is occupied by semistructured data, in which a number of internal structural elements are already distinguished. XML (Extensible Markup Language) is the dominant form of semistructured data today, especially for text documents. Generally speaking, the more structured a data set is, the easier it will be to spatialize it.

Data sets to be spatialized can also be categorized according to how high-dimensional content and relationships are expressed in them. Many data sets are made up of individual elements with a set of n attributes corresponding to dimensions of an n -dimensional space. The notion of *dimensionality reduction* is readily applicable to such data. Examples are census enumeration units and associated attributes. Text documents can likewise be

viewed as existing in an n -dimensional space, with dimensionality determined by the size of the vocabulary.

The second major type of data consists of elements that are explicitly linked to form network structures. Major characteristics of these structures derive from the specific application domain. For example, the files and folders on a hard drive form a hierarchical tree structure. Meanwhile, the networks formed by scientific articles are made up of unidirectional links, with citations always pointing toward past publications. Instead of indicating a specific location in high-dimensional space, network-type data mainly express topological relationships. These are meant to be preserved and conveyed in the low-dimensional display space, and the corresponding methods are known as *spatial layouts*.

Methods of Dimensionality Reduction and Spatial Layout

Broadly interpreted, the term *spatialization* naturally implies turning something that is nonspatial into something that is spatial. To put it more accurately, though, it addresses a transformation *between* different spaces whose main distinction is their dimensionality. People are used to physically navigating and manipulating three-dimensional (3D) space and are likewise able to make sense of visual, geographic representations of that space, which are typically derived from two-dimensional (2D) geometry—sometimes with added elevation values—and stored in GIS databases. The goal of spatialization is to bring the same skills to bear on the complex, high-dimensional data sets that are produced throughout contemporary society. The result is a geometric representation in a low-dimensional, typically 2D or 3D, space that is meant to enable people to detect the patterns, relationships, and trends inherent in high-dimensional data using the perceptual and cognitive abilities that have proven so successful in dealing with geographic space.

Major examples of *dimensionality reduction* techniques commonly used for spatialization include multidimensional scaling (MDS), principal components analysis (PCA), spring models, and the self-organizing map (SOM) method. Among the factors to consider when choosing

among dimensionality reduction methods are scalability (e.g., SOM is applicable to much larger data sets than MDS), performance (e.g., training of large SOMs can take a very long time), and distortion characteristics (e.g., MDS attempts to preserve certain *distance* relationships, while SOM results in the preservation of major *topological* structures).

Among *spatial layout* approaches, the tree map method has enjoyed particular popularity. It takes a tree structure as input and partitions a given rectangular area such that nodes are displayed as areas whose size and color express certain node attributes. Subdivisions are hierarchically stacked in accordance with the tree structure. This method has been popular for visualization of file/folder structures and of the stock market, where the tree structure derives from market sectors (e.g., banking stocks contained in the larger financial sector). There are also a number of graph layout methods, which arrange network nodes and links such that link intersections are largely avoided.

Spatialization Examples

Given the variety of data to which a spatialization strategy may be applied, two different examples are presented here, dealing with text contents and large network structures, respectively.

The first example is based on more than 20,000 abstracts submitted to the annual meetings of the Association of American Geographers (AAG) between 1993 and 2002. This example is quite illustrative of the long series of transformations that is frequently necessary to create a spatialization. In this case, it involved integration of heterogeneous, multitemporal text data; creation of a text index; filtering of the documents and vocabulary; creation of an SOM; storage in a GIS database format; then a series of geometric and attribute manipulations; and finally visualization using GIS software. The result shows major topical subdivisions within this knowledge domain (Figure 1).

The second example is derived from papers published in the *Annals of the Association of American Geographers*. Assume that someone new to geography—the very topic of this encyclopedia—would like to know who the most influential researchers in the field are and how they

connect to form a scholarly research community. The most common approach would be to consult an expert in the field, another would involve going through an introductory textbook on the subject and looking for the names mentioned there. Either way, the results will likely lack objectivity and comprehensiveness. Now, by far the most widely accepted expression of scholarly activity is the publication of original research articles in peer-reviewed journals, which we could presumably consult in our investigation of the geography community. The main impediment to using this resource is the sheer volume of published papers, which makes it impossible to actually survey the field manually. For example, a search of the *ISI Web of Science* database yields 5,956 articles published between 1956 and 2008 in one of the leading geography journals, the *Annals of the Association of American Geographers*. These articles contain 92,000 nonunique references that form a large network of citations (i.e., references from one article to another) as well as a network of cocitations (i.e., articles linked by virtue of being cited together). Spatialization makes it possible to explore the geography knowledge domain through an analysis of such networks. Based on a combination of a spatial layout algorithm with measures of network connectivity, one can derive visualizations of varying types and varying granularity. Apart from the original citations, one could also derive networks of journals or networks of authors. The latter is demonstrated here, with the large co-citation network of authors computationally pruned to contain only the most influential authors and only the most dominant cocitation links (see Figure 2). Node size expresses network centrality, while font size corresponds to the total number of citations of a particular author.

Challenges in Spatialization

There is still a scarcity of spatialization tools that are at the same time easy to use, affordable for most users, and open to modification and integration. Loose coupling of different programs is by far the most common strategy, with relative separation of data preprocessing, dimensionality reduction, geometric transformation, symbolization, and interaction.

Figure 1 Spatialization of the geographic knowledge domain based on 20,000-plus abstracts submitted to the annual meetings of the Association of American Geographers

Source: Author.

When dealing with geographically referenced data, spatialization of n -dimensional attributes should ideally be integrated with other methods of geographic visualization and spatial analysis. However, to date, virtually none of the dimensionality reduction and spatial layout methods mentioned earlier have been integrated into commercial off-the-shelf (COTS) GIS software. Some programming toolkits now include spatialization modules that can be integrated into larger, exploratory visualization environments. The most common roles of COTS GIS in spatialization are the storage of 2D geometry, execution

of various geometric transformations (e.g., surface interpolation), and preparation of visual results.

As spatialization relies heavily on invoking spatial metaphors, much remains to be learned about the specific cognitive mechanisms involved and how to derive from these parameters and guidelines for effective design of spatializations.

Alternative Meanings of Spatialization

Note that *spatialization* is a term that outside of GIScience is sometimes used in different contexts.

Figure 2 Spatialization of a network of influential authors derived from almost 6,000 articles published in the *Annals of the Association of American Geographers* between 1956 and 2008

Source: Author.

One is the use of sophisticated audio technology to create a spatial impression of the direction from which sound is emanating. This is also known as *sound spatialization*. Another notion of spatialization is encountered in the social sciences, where it refers to the process of uncovering the spatial character of human behavior, relations, and events (e.g., the gendering of space).

SPATIALLY INTEGRATED SOCIAL SCIENCE

Spatially integrated social science may be defined as the empirical and theoretical practice where space and place are integrating mechanisms across social science disciplines as well as central considerations both as inputs and as outcomes of theories and models. This definition is rooted in the increasingly implemented practice of examining social, political, and economic data and problems in a spatially explicit context using geographic information systems (GIS), geovisualization, and spatial analysis. Space and place serve as input measures in models and analyses, as spatial concepts (e.g., distance, location, connectivity/topology, proximity) and spatial aggregates of place (e.g., neighborhood and region) are incorporated as units of analysis. In addition, processes that are the targets of inference and models are also very often contingent on space or space-time mechanisms such as diffusion, distance-decay effects, or the creation of social spaces as applications of spatial practice.

Human practices are inherently spatial and create social spaces that take on uses determined by the encompassing society. The connections that link people, institutions, economies, and organizations in geographical space pervade a range of different social contexts that may be conceptualized as general network structures embedded within a social and political context that constitutes the social space. The types, functional scales, and ranges of these connections are generated from spatial practice. Thus, social spaces may consist of everything from political and administrative demarcations referenced directly to geography to transport systems, business and interpersonal interactions, flows, and migrations that occur across a variety of distances and scales, and also global trade and transport networks that may extend over a plethora of network infrastructures. Torsten Hägerstrand's conception of time-geography and space-time behavior prisms as well as his idea of the mean information field are all examples of these social spaces.

Development of Spatially Integrated Social Science

The motivation for spatially integrated social science results from the realization of the necessity of space and geographic context in generating explanations of social, economic, and political phenomena: For example, the processes of trade flow interconnection, migration, capital flows, and compression of space-time due to increased efficiencies of movement have led to the realization of the value of the spatial context in social inquiry. Many practitioners place a growing emphasis on the role of space and place in the activities of analysis and theorizing for contemporary social science. The past 20 years have witnessed a revolution in social science, as geography, space-time, and place/locality have become crucial for understanding the complicated relationships in an increasingly interconnected world.

The social sciences have regularly employed statistical analysis to evaluate hypotheses and make inferences since the halcyon days of the quantitative revolution in the 1960s. However, even when data exhibited a spatial attribution or reference, only rarely was any type of quantitative and cartographic cross-tabulation performed. Partially, this was due to the lack of computer-based cartographic tools (until the advent of SYMAP in 1964 and SYMVU and GRID in the late 1960s) as well as the relative lack of user-ready statistical computer instruments, as most statistical software required some programming for implementation. This situation was further aggravated by the lack of a coherent framework for cogently integrating space and social processes. Social scientists had to wait for the development of integrative computer-based tools such as GIS in the 1980s before spatially referenced data could be readily examined in a geographical context.

Analytical Approaches

Spatially integrated methods provide for the integration of a diverse set of data and tools for analysis. Spatial analysis, place/locality-based analysis, and spatially explicit models and theory are tools of analysis and integration that can be implemented using GIS coupled with a variety of

georeferenced data such as remotely sensed imagery and census unit-based sources, for example. Spatial analysis explicitly incorporates space into statistical models not only to avoid specification problems but also to adequately account for measurable spatial effects. Basic spatial hypotheses regarding space as well as space-time dependence can be established using autocorrelation measures, K functions, and a variety of spatially explicit stochastic and permutation methods. These methods can be used to assess the importance and level of effects of spatial contingency. However, all these methods assume that the processes being measured are homogeneous or stationary over the study area(s).

Place- or locality-based analysis relaxes the process homogeneity assumption and permits local contextual influences to drive the process realizations. Methods such as Markov random field segmentation and geographically weighted regression can be used to evaluate specific local effects in a general-process statistical model. Given these methods and approaches, the importance of space can be measured and evaluated for a range of processes. Spatial effects can then be directly incorporated into the social theorizing activity so that predictions will no longer be assumed to be universal. Theories may account sufficiently for spatial variation so as to be able to predict outcomes differently for different locales. As such, policies based on such social theory may become much more effective and provide society with more tailored solutions to different spatial conditions.

SPATIAL MULTICRITERIA EVALUATION

Spatial multicriteria evaluation (spatial MCE) is based on an integration of theories, methodologies, and software from geographic information systems (GIS) and multicriteria decision analysis (MCDA). Spatial MCE, also known as GIS-MCA or GIS-MCE (multicriteria analysis or evaluation), is well suited to semistructured problems. These problems often require several individuals (e.g., politicians, citizens) to choose from a set of alternatives (e.g., sites, strategies) despite uncertainties regarding how possible solutions should be generated or evaluated. Spatial MCE approaches augment GIS strengths in data management, spatial analysis, and map-based visualization with MCDA techniques that incorporate user judgment into evaluation processes.

Spatial MCE Methodology

The basic procedure that underlies spatial MCE can be summarized as follows:

1. Identifying a set of feasible alternatives
2. Selecting evaluation criteria and standardizing criteria values
3. Generating criteria weights
4. Selecting a decision rule to rank alternatives
5. Testing the sensitivity of the ranks

Identifying Alternatives

Most spatial MCE procedures begin by identifying a set of alternatives or possible solutions to the problem of interest using standard GIS buffer, overlay, and selection functions. Depending on the problem, an alternative may be considered feasible only if it passes all constraints (conjunctive screening) or if it scores sufficiently well on one or more constraints (disjunctive screening).

Selecting Criteria and Standardizing Data Values

A criterion is a measurable characteristic or attribute that is used to judge the performance of each alternative relative to a normative objective (i.e., statement of what is desired). Criteria are represented in spatial MCE as either raster map layers or database fields associated with vector GIS objects. Criteria should be

- complete and minimal (representing all relevant aspects of the problem with the fewest criteria),
- nonredundant (no “double counting” of a specific variable), and
- independent (no autocorrelation of criteria values).
- Once the criteria have been selected, their data values are standardized to a common scale that ranges from 0 (*worst*) to 1 (*best*) to permit trade-offs between criteria. This scaling can be done relative to a maximum data value, a range, or a more complex nonlinear function.

Generating Criteria Weights

Criteria weights allow stakeholders with dissimilar objectives, interests, or experience to express how important they judge a criterion to be relative to other criteria. Criteria weights are expressed as real numbers that range from 0 (*no importance*) to 1 (*highest possible importance*), subject to all weights summing to 1.

Techniques to derive criteria weights vary considerably in mathematical sophistication, theoretical rigor, and cognitive demands. The procedures used most frequently are as follows:

1. Ranking (ordering criteria from least to most important)
2. Rating (distributing a fixed budget of “points” [usually 100] among criteria)
3. Pairwise comparison (comparing all pairs of criteria and indicating the relative importance of criteria through integer ratios)
4. Trade-off (deriving weights from users’ responses to questions of how many units of change in Criterion A they consider equal to a unit of change in Criterion B, and so on)

Applying a Decision Rule

A decision rule is the mathematical approach used to rank alternatives by combining criteria values and weights. Weighted summation is the most frequently used decision rule. It calculates a score for each alternative by multiplying standardized criterion values by their corresponding weights. The results are summed, and alternatives are ranked from the highest score to the lowest. The analytical hierarchy process (AHP) is also popular. It decomposes a problem into a hierarchy of criteria and subcriteria. Alternatives are evaluated in a pairwise manner for each criterion and assigned a score ranging from 1 (*A and B are equally preferred*) to 9 (*A is very strongly preferred to B*). The criteria-based scores are summed to produce overall scores and ranks for each alternative.

Ideal-point analysis (IPA) is based on the general concept from psychological scaling research that an “ideal” value can be identified for each criterion. Each alternative is scored by summing the weighted deviations from each criterion’s “ideal point.” Alternatives that are closer to the ideal solution (i.e., lower total deviations) are preferred.

Outranking techniques compare pairs of alternatives to determine which alternatives dominate all other alternatives. The relative dominance of Alternative A over Alternative B is calculated as the sum of the weights for all criteria where A is

better than B. This is repeated for all other alternatives to produce a concordance value for A. A similar process is used to derive the opposite discordance index. User-specified thresholds are adjusted incrementally to eliminate outranked alternatives and identify the most preferred alternative(s).

Sensitivity Analysis

Sensitivity analysis allows users to examine how sensitive rankings and specific criteria are to small changes to criterion weights. Most spatial MCE software provides functions that allow users to alter weights interactively to determine if rankings are robust or if criteria weights require further consideration.

Criticisms

Academic interest in integrating GIS and MCDM has grown substantially over the past 20 years; however, this enthusiasm is not apparent in commercial GIS. The MCDA component of spatial MCE has been criticized for its “black box” nature that end users find difficult to understand or trust. Others claim that the subjective processes of criteria selection and particularly weighting undermine objectivity in decision making.

Proponents of spatial MCE note that all analyses are subjective to some degree and representing different individuals’ viewpoints explicitly in spatial MCE is a strength. They also note that the process of using spatial MCE can encourage learning, experimentation, and principled negotiation in difficult problem contexts. Reducing barriers to nonexperts’ use of spatial MCE in practice has proven to be more difficult, although advances in software, theory, and application methodologies offer promise.

SPATIAL OPTIMIZATION METHODS

Spatial optimization is concerned with maximizing or minimizing an objective related to a problem of a geographic nature, such as route selection, location-allocation modeling, spatial sampling, and land use allocation, among others. Location-allocation analysis is used to determine optimal locations for one or more facilities with respect to the spatial distribution of demand; applications can range from locating a hazardous waste site or siting a landfill as far as possible from existing population, determining optimal bus stop locations to minimize the walking distance from home, and finding a location for a new cell tower to maximize population coverage to determining a biological reserve for habitat recovery or the optimal location for a recreational site in a neighborhood.

Solving a geographic problem translates into the formulation of an objective function subject to some constraints. For example, in locating bus stops, the objective is to maximize potential ridership. But it may not be possible to locate bus stops everywhere, because geographic space is constrained. Additionally, if potential commuters live farther than a critical distance, they will be discouraged from walking to the nearest bus stop. Another example is finding new locations for a cell tower, where potential locations for new towers may be rather limited because it is desirable not only to locate new base stations at higher elevations to minimize obstructions but also to

ensure that they are not too close to residential areas (because of the not-in-my-backyard [NIMBY] effect).

Single and Multiple Objectives

Different approaches exist to solve geographical problems. Depending on the nature of the problem, a single- or multiple-objective approach can be taken. The optimal location of a recreational site may have a single accessibility objective, to minimize the distance from residential units to the site. In locating an obnoxious facility such as a landfill, the objective may be not only to maximize its distance from population centers but also to minimize transportation costs. Some objectives may be conflicting, and it is often desirable to reach a Pareto-optimal solution, in which no changes can be made without making at least one individual worse off.

Heuristics

Once a problem has been formulated with an objective function and constraints, a solver is generally used to find an optimal solution (e.g., CPLEX, LINGO). Exact solution methods such as integer or linear programming, branch and bound approaches, and Lagrangian relaxation often have limited success, given that an increase in the number of variables will cause an exponential increase in the solution time. In some instances, the size of a spatial problem can create a combinatorial explosion, and heuristic search techniques are preferred. Heuristics are algorithms that are able to find a solution (optimal or not) for a given problem in a limited time frame. Some heuristics reach a suboptimal solution rapidly (e.g., myopic or naive strategy), while others can lead to an optimal solution (simulated annealing, genetic algorithms, tabu search) at the cost of a longer running time. Limited research has been devoted to comparing the benefits and drawbacks of several heuristics and metaheuristics (combination of heuristics) in the context of spatial optimization.

Naive or Random Strategy

The naive strategy randomly chooses a number of locations from a set of candidate locations.

This approach does not account for the structure of the solution space and is therefore very inefficient. Nevertheless, the numerical results following the use of this algorithm provide a good lower bound to evaluate other heuristics.

Total Enumeration

This method consists of evaluating which of all candidate locations optimizes the objective function the best. Total enumeration is sensitive to the size of the problem but is optimal in the one-facility location problem as long as the set of candidate solutions is finite (discrete). The method would, however, be inappropriate when the spatial problem calls for the allocation of more than one facility, because of combinatorial explosion.

Greedy Algorithm

The greedy (or myopic) algorithm starts with a feasible solution. The current solution is then exchanged for another one only if the objective function improves. The process continues until no further improvements can be made. The algorithm is easy to implement and returns a good solution, but the solution may be suboptimal. The algorithm can be effective when applied repeatedly as long as the starting feasible solution is changed.

Simulated Annealing

The greedy approach, as well as the total enumeration in the one-facility location, usually gets stuck in a local optimum, while simulated annealing is able to reach optimality. The major advantage of simulated annealing is its ability to avoid becoming trapped at a local maximum. The algorithm employs not only a stochastic search that accepts changes that improve the objective function but also nonimproving moves, which are accepted with a certain probability. The probability of acceptance decreases as the temperature (or system) cools down.

Tabu Search

Simulated annealing allows nonimproving moves. Tabu search, however, deals with cycling the problems of nonimproving moves, in which

the heuristic momentarily forbids swapping of solutions, which would entail a return to a previously visited solution. The so-called tabu list records these forbidden moves.

Metaheuristics

The combination of two heuristic methods—also called a metaheuristic—allows one to improve on a first solution. For instance, because the greedy heuristic may yield a suboptimal solution, an improvement may be desirable; simulated annealing can use the greedy solution at the start of its optimization procedure.

Genetic Algorithm

A genetic algorithm is a metaheuristic that uses techniques from evolutionary biology to find better solutions at each iteration. The algorithm improves feasible or suboptimal solutions by operations that combine individuals of an improving population. The quality of each individual is evaluated, and several of them are randomly selected from the current solution, based on their solution quality. Solutions are then modified using mutation or crossover to form a new basic feasible solution.

SPATIAL RESOLUTION

Spatial resolution is a measure of the degree of detail in a spatial data set and has been defined variably as the size of the smallest detectable feature, one half the size of the smallest detectable feature, and the minimum angular or linear distance between detectable features. The specific meaning and measurement of spatial resolution varies widely among disciplines and within geography, depending largely on the application area. The key concepts behind spatial resolution are more generally applicable, however, and are important for anyone interested in the study of spatial patterns and processes or mapping. The following sections outline these major concepts, list measures of spatial resolution commonly used by geographers, and discuss briefly the idea of “optimal” spatial resolution.

General Considerations

An increase in spatial resolution (i.e., measurement scale) usually implies a decrease in the geographic extent of the study area (i.e., observational scale). This is primarily due to resource constraints: For example, more time is needed to

Figure 1 Relationship between spatial resolution and other geographically relevant parameters. As spatial resolution increases, other variables increase or decrease. In remote sensing classifications, for example, a decrease in image spatial resolution tends to lead to an increased overestimation of larger features (e.g., forest land) and underestimation of smaller features (e.g., streams).

Source: Author.

collect many samples across larger areas. An increase in spatial resolution normally also implies an increase in map scale (i.e., cartographic scale), because it is impossible to print a map of a large geographic area with fine spatial thematic detail. If map scale and study area extent are held constant, however, changes in spatial resolution have a number of effects on other geospatial product characteristics as well as data acquisition, storage, and processing (Figure 1). Given these effects,

spatial resolution is an important consideration in study design, analysis, and interpretation.

Measures of Spatial Resolution in Geography

Spatial Resolution and Analog Maps

Assuming that a cartographer cannot make a mark smaller than 0.5 mm (millimeter) in size,

Figure 2 Spatial resolution and vector data. The average spatial resolution of this map of counties in the contiguous United States is 46 km. Spatial resolution is much higher in the Eastern United States, however, and the minimum mapping unit that is contained in the GIS cannot even be detected in the printed version of the map.

Source: Author.

the spatial resolution of a hardcopy map can be calculated by dividing the denominator of the representative fraction (map scale) by 2,000. For maps of 1:24,000, 1:100,000, and 1:250,000 scale, the spatial resolution would thus be 12, 50, and 125 m (meters), respectively (the widths on Earth's surface made by 0.5-mm pen lines on these maps). The size of the smallest detectable feature is twice that of the spatial resolution: 24, 100, and 250 m, respectively. Cartographers are also artists, however, and at times include in an enlarged fashion those features that are too small to be detected but too important to be left out.

Spatial Resolution and Vector Data

The size of the minimum mapping unit (MMU), the smallest detectable feature, is often

used to define the spatial resolution of a vector data set. However, the *average* spatial resolution of a vector data set may also be calculated. For point and polygon vector data sets, it is obtained by dividing the square root of the size of the region of interest by the number of observations. County- and state-level maps of the United States would thus have average spatial resolutions of about 54 and 428 km (kilometers), respectively (3,140 counties and 50 states covering a land area of 9,161,923 km² [square kilometers]; Figure 2). The size of the smallest detectable feature on these maps is twice that of the average spatial resolution: 108 and 856 km, respectively. For line vector data sets, the spatial resolution can be estimated by dividing the size of the region of interest by the total length of the linear features.

Figure 3 Spatial resolution and raster data. As the spatial resolution of raster data decreases (*left*: 1 m [meter]; *middle*: 10 m; *right*: 30 m), detectability, information detail, and image clarity decrease visibly. Storage and processing costs also decrease because there are fewer pixels to handle at lower spatial resolutions.

Spatial Resolution and Satellite Images

The spatial resolution of satellite imagery has been measured in many different ways, depending on the user's needs, but most measures fall into one of four categories: (1) measures based on the geometrical properties of the imaging system (e.g., point-spread function), (2) the ability to distinguish between point targets (e.g., Rayleigh criterion), (3) the ability to measure the periodicity of repetitive targets (e.g., modulation transfer function), and (4) the extent of small but finite targets (e.g., effective resolution element). The most commonly used measure falls into the first category and is based on a sensor's instantaneous field of view (IFOV), which determines the area on Earth's surface represented by an individual detector element or pixel at a particular point in time. When measured this way, the spatial resolution

of satellite imagery ranges from about 0.5 m to 1 km (Figure 3). For a feature to be detectable, it should be at least twice as large as the pixel. The quality of a given image for a particular application, however, depends also on many other factors, including but not limited to the spectral resolution, temporal resolution, radiometric resolution, atmospheric conditions, and contrast between features of interest and their surroundings.

Spatial Resolution and Aerial Photography

The spatial resolution of aerial photography is expressed as either sensor system resolution or ground-resolved distance. The sensor system resolution depends primarily on the camera lens and photosensitive material (e.g., the film in an analog camera or charge-coupled device

in a digital camera) and is given in line pairs per millimeter, a measure of the number of resolvable line pairs in the photography. The ground-resolved distance (GR), or smallest resolvable feature on Earth's surface, can be measured as a function of focal length (f), sensor system resolution (RS), and flight altitude above the ground (h): $GR = f \times RS/h$. An air photo acquired from an altitude of 6,000 m with a camera focal length of 150 mm and system resolution of 50 line pairs/mm would thus have a ground-resolved distance of 1.25 line pairs/m. In accordance with the above measures of spatial resolution, the spatial resolution of aerial photography is one half the ground-resolved distance: that is, 0.625 m in the example. It typically ranges from about 10 centimeters to 5 m.

Spatial Resolution and Field Data

In the context of field data, spatial resolution typically refers to the size of the sample unit (e.g., the size of a quadrat in ecological studies). Spatial

resolution may also be calculated from the distance between point samples in a given area (i.e., spatial sampling rate) using the formula for point vector data sets given above.

What Is the Optimal Spatial Resolution?

The optimal spatial resolution is the one that is most suitable to meet a study's objectives. It has to be fine enough to facilitate the detection of features of interest and to capture the patterns caused by processes of interest (i.e., the operational scale, or "scale of action"). Too fine a spatial resolution, however, is wasteful in terms of resource requirements and may convey excessive information (i.e., noise) that does not reveal anything relevant about the subject of interest. Then again, while it is possible to decrease the spatial resolution of a data set, it is impossible to acquire greater information content by increasing the spatial resolution of the original data set: Spatial resolution is finite.

SPATIAL STATISTICS

The term *spatial statistics* encompasses the statistical processes used to analyze spatial data by incorporating spatial information. It involves the statistical analysis of spatial data. It has been successfully used in various fields for analyzing spatial patterns not evident by merely mapping the distribution over space. Over the years, the importance of incorporating the spatial component in drawing meaningful references for data points distributed over space has become increasingly evident. The long-established methods in classical statistics, though extremely useful for detailed interpretation of large data sets, are not able to account for spatial relationships in the distribution. Typical statistical measures most often do not incorporate the underlying spatial relationships among different variables. As a result, results drawn by classical statistical methods may not provide the actual explanation of the problem under study. With the advent of geographic information system (GIS) tools, it has become possible to compute more complex statistics taking into consideration the spatial relationships among variables. Thus, one of the main objectives of spatial statistics includes the reduction of spatial patterns into concise and clear summaries. Moreover, spatial statistics includes all classical areas of statistics, consisting of design, statistical methods, stochastic modeling, and statistical analysis. The main components of spatial statistics are described briefly in the following sections.

Spatial Data

As mentioned above, spatial statistics includes spatial data analysis. *Spatial data* may be defined as a database that contains information about certain variables and their distribution over space. In other words, a *spatial data set* consists of each record or observation accompanied by its spatial coordinates in the form of latitude and longitude or x and y coordinates as well as topology information. It can also be defined as data pertaining to location, shape, and geographical relationships. Thus, spatial statistics consists of the study of spatially referenced data that can be mapped digitally. Spatial data are represented typically in the form of points,

lines, and polygons (including raster cells), with associated attribute information about each displayed spatial unit. Among the most important and commonly used measures in classical statistics are measures of central tendency, which include mean, median, and mode. However, these measures are not able to take into consideration the spatial locations in the final results. In spatial statistics, these essential statistical measures have been modified to include the individual location information in the final results. For instance, spatial mean can be used to determine the mean center or average center of a set of observations. Similarly, the concept of median has been extended to include the concept of the median center, which is mainly used for determining the spatial median of a set of observations.

Spatial Autocorrelation

In view of one of the main objectives of spatial statistics, which is the analysis of spatial patterns, there are different types of spatial patterns that may exist over space. These patterns include heterogeneous patterns (patterns that vary in a systematic manner from place to place), anisotropy (where there is directional bias in a particular spatial pattern), and clustering effects (where locations with similar attribute values are clustered close together). One of the main components of spatial statistics, as emphasized before, is the study of the underlying spatial relationships between different variables, collectively referred to as *spatial autocorrelation*. It is a function of similarities in both location and attribute values among the different data observations. *Autocorrelation* refers to the pairwise correlation of univariate observations; in more general terms, it can be referred to as self-correlation. Therefore, spatial autocorrelation refers to the spatial distribution of autocorrelation among different observations. This type of autocorrelation arises as a result of some form of ordering in the spatial distribution of variables. Spatial autocorrelation coefficients help in examining the clustering of a given set of observations based on attribute values. It is expressed in the form of positive and negative autocorrelations. Positive autocorrelation occurs when locations with similar attribute values that are clustered have more similar characteristics, while negative

Figure 1 Hypothetical example showing different forms of spatial autocorrelation: (A) significant positive spatial autocorrelation, (B) spatial independence implying no spatial autocorrelation, and (C) significant negative spatial autocorrelation

Source: Goodchild, M. F. (1986). *Spatial autocorrelation (CATMOG)*. Norwich, UK: GeoBooks.

autocorrelation occurs when attribute values of observations located close together are dissimilar. Two of the most effectively used measures of spatial autocorrelation are Geary's ratio and Moran's *I*. Both measures check for spatial autocorrelation by taking into consideration attribute value similarity and location proximity. Furthermore, the concept of spatial autocorrelation does not ignore randomness; rather, it takes into consideration both spatial pattern and error. Figure 1 shows hypothetical examples of different types of spatial autocorrelation.

Geostatistics

Geostatistics is an integral component of spatial statistics. Geostatistics involves the prediction of unknown values at given locations or of aggregation across given regions. Geostatistics has also been defined as a method of taking into consideration the geographic configuration while conducting any statistical analysis. Furthermore, it also involves smoothing and interpolation that enables the prediction and mapping of unknown values at specific locations. The process of making predictions for unknown surfaces includes modeling the spatial relationships among the different locations. To accurately model spatial data,

one needs to carry out extensive exploratory spatial data analysis (ESDA) of the spatial data set under study. ESDA mainly includes viewing a spatial data set in detail to identify the general distribution of the data, for example, plotting frequency distributions of the data set, from which specific details about the spread of the data set can be analyzed. ESDA also enables the identification of spatial outliers among a given set of data measurements. Furthermore, it may also be used to identify any form of global or local trend, as well as any directional bias in the data set. Therefore, the results from ESDA analysis are extremely useful for conducting geostatistical analysis and also in the final selection of the surface analysis model.

Geostatistical analysis of spatial data occurs in two phases. The first phase consists of modeling the semivariogram or covariance to analyze surface properties for a particular spatial data set. The second phase consists of interpolating the data to predict values for unknown locations. Commonly used techniques for spatial interpolation include different forms of kriging, which creates continuous surfaces using the statistical relationships among the known observations—for example, ordinary, simple, universal, probability, indicator, and disjunctive kriging. The

results of kriging also include the creation of prediction and error surfaces, which enables the researcher to assess the effectiveness of the model used in creating the prediction surfaces. An example of the application of geostatistics in the form of surface interpolation techniques is given in Figure 2.

SPATIAL STRATEGIES OF CONSERVATION

Geographers have had plenty to say about the spatial strategies of conservation. Their contributions can be loosely categorized into two main approaches. The first has origins in resource management and draws strongly from biogeography, while the second has origins in critical approaches to the study of human-environment relations (e.g., political ecology). While their differences and distinct contributions are outlined in this entry, it is clear that both groups agree that conservation is an inherently spatial process. The conservation of targeted flora and fauna as well as entire ecosystems is often accomplished through policies that are explicitly spatial: land use zoning, protected areas, buffer areas, and wildlife corridors. These strategies require the delineation of boundaries that separate the protected from the not protected. Furthermore, those conservation mechanisms that are not spatial in origin (e.g., pesticide bans, emissions restrictions, and carbon trading) have spatial outcomes; they take place somewhere (and not somewhere else), and they play a role in shaping the spatiality of related social and economic activities. The treatment of these geographies of conservation, however, differs substantially between the two approaches.

The resource management stream of geography concentrates its effort on how to address already accepted problems of conservation: how to prevent habitat fragmentation, protect biodiversity, and minimize damage to nature by people. To these ends, emphasis is often on how best to characterize the existing fragmentation using geographic information systems and remote sensing, as well as on the location and functionality of protected-area boundaries and buffer zones. For species-specific conservation, the concern is often with the spatial needs of a particular species and the extent and quality of their habitats. It is important to note that the spatial solutions to these conservation problems are largely territorial; that is, they support the creation of territories dedicated to conservation goals such as national parks, wildlife corridors, and ecological zones.

The single large or several small (SLOSS) debate, beginning in the 1970s and persisting in various permutations today, is indicative of this

approach. The debate centers on whether, as a general rule in instances of habitat fragmentation, creation of SLOSS reserves is the best spatial strategy to ensure long-term biodiversity preservation. The answer to this question varies significantly depending on the particular set of circumstances and the ecosystem in question but almost always takes into account the species-area curve from the theory of island biogeography, the diversity of habitats available, and any edge effects that may help or hinder species diversity.

Geographers more closely associated with critical approaches to human-environment relations, such as in political ecology, question the spatial solutions offered by the resource management approach discussed above. They suggest that the delineation of boundaries separating biota that are to be targeted for conservation from biota that are not is a spatial reification of the nature-culture dichotomy and consequently fails to recognize nature as at least a partially social artifact, consistent with social construction of nature arguments. Furthermore, such strategies are deemed to perpetuate unnecessary violence against rural people, particularly indigenous peoples, by separating them from their livelihood. Much research has been conducted, for example, on the impacts of boundary delimitation, protected-area establishment, and conservation policy and their associated voluntary and involuntary displacement. Such critique has focused largely on conservation practices in the developing world, which are seen as coercive and motivated as much by political as by environmental goals.

In addition to exploring the social impacts and political motivations of the boundary demarcation associated with territorial conservation mechanisms, critical approaches have also investigated the spatiality of indigenous, local, and peasant conservation strategies. In contrast to the simple spatial form of parks, protected areas, buffer zones, and corridors, authors have found less managerial forms of conservation to be more spatially complex. Resource use and conservation practices embedded within local social-ecological systems are often species specific and contingent on season, gender, and livelihood group. So, rather than easily legible, impermeably bounded zones of conservation, local conservation management often consists of porously bounded,

overlapping, dynamic zones subject to social relations. The exceptions to this spatial flexibility are sacred groves, cemetery forests, and other areas deemed off limits.

In short, spatial strategies of conservation can and do vary tremendously, and they tend to be consistent with the management goals of the implementing institutions. If conservation goals include limiting or eliminating human use and are managed through a centralized process indicative of state or large nongovernmental organizations, firmly bounded zones separating humans from nature are often the spatial strategy of choice. In cases where conservation goals that see human use of resources as integral, or at least not antithetical, to conservation are implemented through decentralized processes of land management where the managers are present in the landscape, spatially flexible and complex strategies are more likely to be successful.

Most recently, and as a partial reflection of a neoliberal turn in environmental governance, nonterritorial forms of conservation are gaining popularity. These include certification schemes for environmental products and restrictions on agricultural inputs and green development, and they reflect a shift toward sustainability as a primary conservation goal. Such mechanisms are not aspatial but rather tend to de-emphasize the fixed, impermeable boundaries of protected areas in favor of a spatiality produced through the cross-scale articulation of particular target landscapes, livelihoods, and global markets. This trend speaks to a future of conservation governance that makes use of a full range of spatial strategies, combining statically bounded territories of conservation with more diffuse spatial strategies that both limit and encourage particular kinds of activities in particular kinds of spaces.

SPATIAL TURN

In the late 20th century, human geography underwent a profound conceptual and methodological renaissance that transformed it into one of the most dynamic, innovative, and influential of the social sciences. The discipline, which had long suffered from a negative popular reputation as a trivial, purely empirical field with little analytical substance, moved from being an importer of ideas from other fields to an exporter, and geographers are increasingly being read by scholars in the humanities and other social sciences. As a result of the rebirth in scholarship in geography, other disciplines have increasingly come to regard space as an important dimension of their own areas of inquiry, in what is widely called the spatial turn. Denis Cosgrove (1999), for example, argues that

a widely acknowledged “spatial turn” across arts and sciences corresponds to post-structuralist agnosticism about both naturalistic and universal explanations and about single-voiced historical narratives, and to the concomitant recognition that position and context are centrally and inescapably implicated in all constructions of knowledge. (p. 2)

Recent works in the fields of literary and cultural studies, sociology, political science, anthropology, history, and art history have become increasingly spatial in their orientation.

In some ways, this transformation is expressed in simple semantic terms, that is, in the rising popularity of words such as *space*, *place*, *location*, *positionality*, and *mapping* in denoting a geographic dimension. In other ways, however, the spatial turn is much more substantive, involving a reworking of the very notion and significance of spatiality to offer a perspective in which space is every bit as important as time in the unfolding of human affairs, a view in which geography is not relegated to an afterthought of social relations but is intimately involved in their construction. Geography matters, not for the simplistic and overly used reason that everything happens in space but because *where* things happen is critical to knowing *how* and *why* they happen.

With space and place at the center of the analytical agenda, geographical thought has arguably played a major role in helping facilitate interdisciplinary inquiry that offers a richer, more contextualized understanding of human experience, social relations, and the production of culture. As different disciplines have taken up geography in their own way, they bring to bear their respective assumptions, languages, paradigms, applications, and examples on the meaning of the spatial. Thus, as the spatial turn has unfolded across the social sciences and humanities, it has come to embrace an ever-larger set of uses and implications.

The Historical Fall and Rise of Spatiality

In the 19th century, space became steadily subordinated to time in modern consciousness, a phenomenon that reflected the enormous time-space compression of the Industrial Revolution; intellectually, this phenomenon was manifested through the lens of historicism. Typically, historicist thought linearized time and marginalized space by positing the existence of temporal “stages” of development, a view that portrayed the past as the progressive, inexorable ascent from savagery to civilization, simplicity to complexity, primitiveness to civilization. Historicists such as Georg Hegel, Karl Marx, and Arnold Toynbee offered sweeping teleological accounts that paid little attention to space, human consciousness, or the contingency of social life. In the same vein, social Darwinism usurped the original theory of evolution as contingent and

open ended, substituting it with a simplistic, racist, linear view such as Herbert Spencer’s “survival of the fittest.” Orientalist thought structured the Western geographical imagination such that distance from Europe became equated with increasingly more primitive stages of development, conflating continents with races in terms that were hierarchically organized with respect to their alleged degree of temporal progress. In this way did historicism eclipse space in the service of imperial thought: Beyond Europe was *before* Europe, a theme articulated again in modernization theory and its current neoliberal variants.

The reassertion of space into the modern consciousness was a long, slow, and painful undertaking. In the 1920s, the Chicago School of sociologists and geographers began to inject space into urban analysis, a project that was poignant in its sensitivity to the experience of recent immigrants and the textures of ethnic neighborhoods and simultaneously doomed by its simplistic understanding of class, gender, power, and the world system. In the tumultuous 1960s, the seminal works of Henri Lefebvre and Michel Foucault were critical in suggesting that the organization of space was central to the structure and functioning of capitalism as a coherent whole. Moreover, Lefebvre maintained that space must be understood not simply as a concrete, material object but also as an ideological, lived, and subjective one.

It was social theory—specifically Marxism, initially via the works of David Harvey—that formed the centerpiece for a critical reevaluation of space and spatiality in social thought. Social theory repositioned the understanding of space from given to produced, calling attention to its role in the construction and transformation of social life and its deeply power-laden nature. Harvey’s spatialization of Marxism, and concurrent Marxification of space, centered on the deep structure of commodity production and the conversion of commodities into money, generating a model of production and the labor process that shed light on their transformation of time and space. Landscapes, in this reading, reflected the logic of commodity production at any given historical moment, constituting a “spatial fix” or window of stability that enabled the process of commodity production to unfold unproblematically, at least temporarily.

This line of thought was picked up and advanced by Edward Soja, whose works emphatically insisted that the spatial could not be subordinated to the temporal or the social. Thus, he maintains that social theory should rest on the triangular foundations of time, space, and social structure, each of which contingently structures and is structured by the others. Soja argues that the spatial turn has involved the end of historicism and the reassertion of space into social theory. In a sense, this trend marks a return to Immanuel Kant's position that held the two dimensions to be of equal significance. Similarly, Manuel Castells, noting the pronounced degree to which postmodern capitalism relies on information as its primary resource, distinguished earlier *information societies*, in which productivity was derived from access to energy and the manipulation of materials, from later *informational societies* that emerged in the late 20th century, in which productivity is derived primarily from knowledge and information. In his reading, the spatiality of postmodernism was manifested in the global "space of flows." He notes, for example, that while people live in places, postmodern power is manifested in the linkages among places, their interconnectedness, as personified by business executives shuttling among global cities and using the Internet to weave complex geographies of knowledge invisible to almost all ordinary citizens. This process was largely driven by the needs of the transnational class of the powerful employed in information-intensive occupations.

Why the Spatial Turn?

The spatial turn reflects broader transformations in the economy, politics, and culture of the contemporary world. We cannot understand the production of spatial ideas independently of the production of spatiality—that is, views of geography are only comprehensible by appeal to the social and spatial contexts. Several forces have intersected to elevate space to new levels of material and ideological significance.

Contemporary globalization has undermined commonly held notions of Euclidean space by forming linkages among disparate producers and consumers intimately connected over vast

distances through flows of capital and goods. *Globalization* is an ambiguous term, however, and refers to a variety of processes that play out in different ways, from global cities to international trade to the internationalization of culture and consumption. Unprecedented volumes of immigration across national borders have increasingly confronted residents in many countries, particularly in Europe and North America, with issues of cultural difference. Tourism likewise allows for selective appropriation of distant cultures and places. The global media relay news and events across a global stage. The offshoring of many jobs from the developed world to the developing one has called attention to national differentials in skills and labor costs. International finance, a worldwide space of flows, global deregulation, and the decline in transport costs have all conspired to erode conventional geographic pre-occupations with proximity. Far from annihilating the importance of space, globalization has increased it. Ironically, just as several pundits announced the "death of distance" and the "end of geography," geography acquired a renewed significance in the analysis of international flows of information, culture, capital, and people. As neoliberal capital operates ever more effortlessly on a worldwide stage, small differences among regions become increasingly important. Moreover, as numerous scholars have shown, globalization does not play out identically in different places; rather, context matters, and the incorporation of unique places into the global division of labor changes not only those locales but also the world system as well. Glocalization, therefore, is a two-way street.

The rise of cyberspace and the Internet has also raised issues of spatiality in several fields. The Internet, an unregulated electronic network connecting an estimated 1.5 billion people in more than 200 countries in 2008, allows users to transcend distance virtually instantaneously. Telecommunications systems have become the central technology of postmodern capitalism, vital not only to corporations large and small but also to consumption, personal communication, entertainment, education, politics, and numerous other domains of social life. Indeed, for many people who spend a great deal of time in the digital world, cyberspace has become such an important part of

everyday life that the once solid boundary between the real and the virtual has essentially dissolved: It is difficult today to tell where one ends and the other begins. In allowing people and firms to “jump scale,” to connect effortlessly with others around the world at the click of a mouse, cyberspace has been instrumental in the production of complex, fragmented, jumbled spaces of postmodernity, all of which have called for mounting scrutiny. Similarly, geographic information systems (GIS) offer dramatic new means to analyze spatiality, even if these are often drenched in empiricist and positivist epistemologies. GIS, therefore, is not simply reflective of the new importance of space but also constitutive of it.

Finally, the rapidly rising seriousness of global ecological and environmental problems has played no small role in elevating the significance of space. Issues that once could be understood and contained within relatively localized contexts, such as water pollution, are increasingly viewed as approachable only on a worldwide basis. Acid rain crosses national borders with ease. The enormous crisis of biodiversity unfolding across the world is inseparable from global patterns of habitat destruction, deforestation, and resource consumption. The gradual end of the age of cheap petrochemicals has added new urgency to this issue and threatens to raise the “friction of distance” of commuting fields. Looming over all this is the dark shadow of global warming: As evidence mounts daily of rapidly melting ice caps and glaciers and of ecosystems turned upside down overnight, the location of the sources of greenhouse gases has become a vitally problematic issue. Because environmental issues are unevenly distributed across space and because geography as a discipline has a long history of investigating human-environment interactions, space and spatiality have become crucial dimensions in understanding and tackling these problems.

SPECIES-AREA RELATIONSHIP

The species-area relationship is the positive relationship between the number of species and the size of the area in which they live. As the area increases, the number of species that are found within the area of interest also increases. The number of species found in an area is referred to as species richness. The species-area relationship is a general and widely documented pattern of community ecology and biogeography. It has become so well accepted that it is sometimes referred to as a rule or a law. Due to its fundamental importance in describing ecological relationships, the species-area relationship has been prominently incorporated into models of island biogeography and has been used in conservation decisions.

Fundamentally, the species-area relationship is a very simple conceptual relationship between species richness and area. When a small area of a landscape is observed, only a few of the species within the landscape will be included within the boundaries of the area. These species are likely the more common species within the landscape. As the observed area is expanded, it is more likely to include some of the rarer species in the landscape, thus increasing the observed species richness. Once a starting point is defined and the study area is expanded around that point, species richness will never decline. The number of species either increases as the study area increases or

remains the same. Even if the loss of species occurs within an area through time, the relationship between species richness and area within each time snapshot will not be negative.

While the species-area relationship is a positive relationship between species richness and area, the relationship is not linear. As the observed area is expanded and more rare species are observed, the number of unrecorded species in the landscape declines, and fewer additions to the species richness value occur. This relationship was modeled in 1920 by Arrhenius as

$$S = cA^z,$$

where S is the species richness, c is a constant, A is the area, and z is a fitted value that represents the slope of the linear relationship for the log of the equation. This model is better known as the *power model*. Another common model used to describe the relationship between species richness and area is the Gleason model, which was developed in 1922. The equation of the Gleason model is

$$S = d + k \log(A),$$

where S is the species richness, d is the y -intercept, k is the slope of the line, and A is the area. Both equations have been used extensively to describe how species richness increases as area increases, but neither is considered to be applicable in all cases. A major criticism of both equations is that they do not approach a maximum species richness value as area increases. In theory, there are a limited number of species within a landscape, but both the Arrhenius and Gleason models allow species richness to increase without limit as area increases. While in a practical sense, there will be a limit to the area that is being studied, thus making the Arrhenius and Gleason models not completely applicable in most studies, it is important to recognize that the models are just representations of the observed relationship between species richness and area. The inherent flexibility of the equations allows them to be fitted to maximize their representation of a data set. They are tools to quantitatively describe how species richness increases as area increases.

One of the most well-known applications of the species-area relationship is the area effect for the equilibrium model of island biogeography.

This model is also known as the MacArthur-Wilson model, after Robert H. MacArthur and Edward O. Wilson, who popularized the model in the 1960s. The equilibrium model of island biogeography predicts the number of species that should exist on an island that is in equilibrium based on the size of the island, the distance of the island from the mainland, and the turnover of species richness for the island. This model uses the species-area relationship as the area effect to predict that larger islands can support more species than smaller islands. This is used in concert with the distance effect to factor size and location into the equilibrium species richness value for an island. The distance effect is the assumption that islands closer to the mainland have more species than islands that are farther from the mainland.

The distance effect and the area effect have an impact on the number of species on an island at equilibrium through their effects on species immigration and extinction rates. If two islands, one small and one large, are at the same distance from a mainland, the expected immigration rate is the same for both islands, but the larger island is expected to support larger population sizes, which in turn lowers the extinction rate. This results in the larger island having a larger expected species richness value when it is at equilibrium and follows the basic premise of the species-area relationship. If two islands are the same size, but one is closer to the mainland than the other, the immigration rate is expected to be greater for the island closer to the mainland, while the extinction rates for the islands would be the same due to their areas supporting the same population sizes. This results in a higher expected species richness value for the island that is closer to the mainland and is the consequence of the distance effect.

The basic equilibrium model of island biogeography takes area's impact on extinction and distance's impact on immigration into account, but area can also be considered to affect species immigration to an island, just as distance's impact on extinction can also be considered. Larger islands might have greater immigration rates than small islands due to the increased potential for species to find larger islands. This potential impact is known as the target effect. Increased distance, or isolation, of islands might increase the extinction rates for those islands in addition to the predicted

lower immigration rates of the basic equilibrium model of island biogeography. This increase in extinction rates with increasing isolation is known as the rescue effect.

The simplicity of the basic equilibrium model of island biogeography has resulted in numerous criticisms of the model. One of the practical issues with the model is the difficulty in quantifying the immigration and extinction rates for islands. Extensive fieldwork is required to estimate these rates, and they may change with time, which would change the predicted species richness equilibrium. The model also ignores the potential impacts that species may have on each other. Some species may cause the extinction of other species on an island, prevent certain species from immigrating to the island, or interact with species in other ways to influence the species richness of the island. Other scenarios that violate the assumptions of the basic equilibrium model of island biogeography are speciation events on islands that increase species richness without immigration; an uneven distribution of species on the mainland, which would affect immigration rates to islands; and varying habitats on the islands, which would influence both the number of species that could immigrate to the various islands and the rates of extinction on the islands. Despite these criticisms, the basic equilibrium model of island biogeography is regarded as a very useful conceptual tool for understanding how area, distance, and species immigration and extinction affect species richness on islands.

Islands are especially good features with which to examine the species-area relationship because the shores of the islands already define the boundaries of the study areas. It can be problematic to study the species-area relationship on large landmasses because it is more difficult to justify the study areas that are chosen. On large landmasses, the area in which species richness is being counted is likely to be selected from a larger contiguous habitat or to contain multiple habitats that each have their own processes that influence species richness. This makes it very difficult to compare species-area relationships between studies. Islands have inherent boundaries and thus make natural individual units to study and observe relationships. One such relationship for oceanic islands, known as Darlington's rule, states that a 10-fold

increase in the area of an island results in the doubling of the species richness. The studies that have looked at the species-area relationships within large landmasses have focused on areas that are easily distinguished from their surrounding habitat forms. Two examples of these types of areas are mountaintops and lakes. These areas are similar to islands in their readily defined boundaries and their patchy distributions.

Another inland landscape that can use the island model is a fragmented habitat. Habitat fragments can act as islands for species that require the presence of other species that only exist within the fragmented remnants of a formerly continuous habitat. Modern conservation efforts have sometimes used the species-area relationship as a basis for determining what areas to focus on protecting from commercial interests. This is typified by the single large or several small (SLOSS) reserve debate of the 1970s and 1980s. This debate centered on whether a single large nature preserve or several small preserves would maximize the number of conserved species. The rationale for preserving the largest areas of land is that according to the basic equilibrium model of island biogeography, maximizing area also maximizes species richness. This approach has been criticized for not taking into account the inherent differences in species richness between habitats and in species population sizes within habitats and the relative scarcity of different habitats. Selecting a large area of land to conserve over several small areas may not conserve more species if the species in the small areas do not exist in any other locations, if there is a greater species richness inherent in the small areas, or if a number of species in the large land area have small population sizes, which put them in danger of becoming extinct. Ultimately, the optimal spatial design of preserves depends on the characteristics of the species within the communities being conserved. This can include spatial patterns that are not included in the SLOSS debate. The species-area relationship is a widely observed general relationship between area and species richness, but many factors other than area influence species richness and the long-term persistence of species within a habitat, and these need to be considered in conservation and land management decisions.

SPECTRAL CHARACTERISTICS OF TERRESTRIAL SURFACES

Terrestrial surfaces are composed of a diverse assemblage of human-made materials such as concrete, asphalt, and metal and natural materials such as soils, shrubs, and trees. Scientists observe such features on the surface of the Earth and make measurements to better understand the characteristics associated with them. This entry describes the nature of research using remote sensing and examines the spectral characteristics of vegetation, soil, water, and human-made materials.

Characterizing and monitoring the materials through time is very important for many Earth resource management applications. While the tasks are often conducted by taking detailed field measurements, the process is time and labor intensive and is often difficult to conduct over large geographic areas. Remote sensing, which collects information about a feature without being in direct physical contact with it, has been widely used for conducting the tasks in an efficient way. Spectral remote sensor systems have

matured from simple panchromatic sensors (single band in gray scale) to multispectral sensors (multiple bands, generally between 3 and 15) and further to hyperspectral or ultraspectral sensors, which collect spectral data in up to hundreds and thousands of bands in the electromagnetic spectrum. As the spectral resolution (e.g., 10 nm [nanometers]) of sensor systems improves, we can get a more accurate spectral response for an object under examination. Because each material on the surface of the Earth has a unique spectral pattern in the electromagnetic spectrum, it is important to understand the spectral characteristics of the key materials that are easily found on terrestrial surfaces. It is believed that many of the biophysical and human-made materials under investigation have unique absorption features with 10 to 20 nm width. The following sections will look into the spectral characteristics of selected natural and human-made materials, focusing on the visible, near-infrared, and middle-infrared regions (i.e., 400–2,500 nm) of the electromagnetic spectrum.

Spectral Characteristics of Natural Materials

Three major materials found on the terrestrial surfaces include vegetation, soil, and water. Each of the materials has a distinctive spectral reflectance pattern.

Vegetation

Vegetation is one of the most important components of Earth's ecosystems, since it covers much of the terrestrial surface. Vegetation has various absorption features, such as chlorophyll (430 and 660 nm for chlorophyll *a*; 460 and 640 nm for chlorophyll *b*) and water (around 1,400–1,900 nm) absorption. That is why reflectance is relatively low in those regions. Green energy (around 500–600 nm) between the two chlorophyll absorption bands in the blue and red regions is relatively less absorbed by leaves. Thus, healthy vegetation (i.e., foliage) generally appears to be green to human eyes. Healthy vegetation exhibits dramatic reflectance increase in the near-infrared

region (700–1,200 nm) due to the internal scattering at the cell wall–air interfaces within leaves. Abrupt reflectance increase between the red and near-infrared regions (680–780 nm) is a unique spectral characteristic of vegetation. This region is known as red edge and is highly related to vegetation characteristics such as chlorophyll content and biomass. For example, a shift in the red-edge position may be due to phenological change or vegetation stress. The spectral pattern of vegetation can be influenced by many factors such as nutrient/water stress, disease, and the phenological cycle of vegetation. Thus, the spectral characteristics of vegetation and their change have been widely studied to detect and monitor vegetation health.

Soil

Dry, bare soil generally exhibits a gradual increase in reflectance with increasing wavelength between 400 and 2,500 nm. Many factors determine the spectral characteristics of soil, including particle size, texture, moisture, organic matter content, and surface roughness. For example, as soil moisture increases, incident electromagnetic energy is absorbed by water, resulting in a lower soil reflectance curve. Similarly, the greater the organic matter content of a soil, the lower the spectral reflectance.

Water

Water absorbs most of the incident radiant flux, especially in the near- and middle-infrared regions. Thus, scientists often use near- or middle-infrared bands to delineate water bodies from remote sensing data. If water does not contain organic and inorganic constituents and is relatively deep, it appears very dark throughout the visible, near-infrared, and middle-infrared regions. However, many natural water bodies inherently contain various kinds of organic and inorganic constituents, such as chlorophyll *a* and suspended sediment. These constituents generally result in spectral reflectance increase, particularly in the visible region. Consequently, water color in the visible region (and a portion of the near-infrared region) has been intensively studied to address water quality issues. Light at

the short-wavelength regions (i.e., blue to green) penetrates water bodies to some extent. That is why we can easily identify the bottom topography of water bodies in shallow areas using the blue and green bands. Green light (i.e., centered at 540 nm) is often used to measure water depth because of its ability to penetrate water.

Spectral Characteristics of Human-Made Materials

Human-made materials easily found on terrestrial surfaces are generally impervious. Human-made impervious surfaces such as asphalt pavement have greatly affected environmental resources such as urban air and water. They have also increased the frequency of disaster: for example, flooding due to excessive runoff. In addition, many impervious materials such as asphalt keep rain from infiltrating into the ground and eliminate natural groundwater recharge. Scientists have used spectral remote sensing to identify and manage impervious surfaces in an efficient and timely manner as well as to conserve environmental resources. Typical human-made materials include asphalt, concrete, and steel.

New asphalt pavement has very low reflectance characteristics throughout the visible, near-infrared, and middle-infrared regions. Although asphalt may result in spectral variation in the visible and near-infrared regions with the different deterioration levels over time, it generally appears very dark, even black. Concrete has relatively high reflectance characteristics throughout the visible, near-infrared, and middle-infrared regions. The spectral reflectance of steel is also high, between 400 and 2,500 nm, and it varies by the levels of oxidation and galvanization.

Image pixels with an assemblage of these human-made materials, often found in an urban area, typically appear steel-gray on false color composite images using green, red, and near-infrared bands. Since the spectral reflectance characteristics of these human-made materials are quite different from those of natural (biophysical) materials, scientists have widely used spectral data to identify and classify various land cover features.

Some scientists refer to the spectral pattern of a material as a spectral signature (i.e., a spectral

fingerprint of the material). However, it should be noted that the spectral characteristics of a material, either natural or human-made, vary with many factors, including its condition and data collection date and time. Nonetheless, the spectral characteristics of materials on terrestrial surfaces provide a unique opportunity to efficiently identify and monitor the materials, which allows us to better understand the dynamics of Earth's systems.

Earth's surface features is recorded. In broad terms, the narrower the wavelength interval for a particular band or channel, the finer the spectral resolution. The spectral resolution of a remote sensing sensor depends primarily on two factors. The first is the number of bands or channels used and the second is the width or wavelength interval assigned to each band or channel. Higher spectral resolution can be achieved from using a larger number of bands and by assigning a narrower width for each band; however, the spectral position of a band is also important for achieving high spectral resolution. Narrow bandwidth is generally obtained by dispersing the spectrum of incoming radiation on to an array of detectors using prisms or diffraction gratings.

The spectral resolution of a standard black-and-white film is fairly coarse as the spectral sensitivity of the film is restricted to the incident energy in wavelengths extending over the entire visible portion of the spectrum and the various wavelengths of the visible spectrum (i.e., ~0.4–0.7 μm [micrometers]) are not individually distinguishable. That is, black-and-white film records only the overall energy in the entire visible portion of the spectrum. Color film, on the other hand, is sensitive to the incident energy within the blue, green, and red wavelengths of the visible spectrum and therefore has relatively higher spectral resolution. It can discriminate between features of various colors based on their reflectance in each of these distinct wavelength regions.

Most satellite-based as well as airborne remote sensing systems designed for observing Earth's surface features record energy response in several discrete spectral bands at various spectral resolutions (Figure 1). These systems are commonly referred to as multispectral sensors. Landsat's thematic mapper (TM), for example, records electromagnetic energy reflected by and emitted from Earth's surface features in seven discrete bands covering the visible through thermal-infrared portions of the spectrum. The Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), on the other hand, is designed to provide spectral resolution of Earth's surface features in 14 discrete bands. It has 11 bands to cover the middle-infrared through thermal-infrared portions of the spectrum, compared with only three bands available to cover the same regions on Landsat's TM.

SPECTRAL RESOLUTION

The term *spectral resolution* refers to the number and width of a specific wavelength interval (i.e., band or channel) in the electromagnetic spectrum to which a remote sensing system is sensitive. Spectral resolution describes the ability of a sensor to define the fine wavelength intervals in which electromagnetic energy reflected or emitted from

Figure 1 A graph showing the spectral properties of different features in visible through middle-infrared bands of the Advanced Spaceborne Thermal Emission and Reflection Radiometer

Source: Author.

- Multispectral - tens of bands available (large slivers of major spectral regions)

- Hyperspectral - hundreds of bands available (smaller slivers of major regions)

Figure 2 Multispectral sensor versus hyperspectral sensor

Source: Author.

New advanced hyperspectral sensors are designed to detect reflected or emitted energy in hundreds of narrowly defined (i.e., narrow bandwidth) contiguous spectral bands (Figure 2). The Airborne Visible Infrared Imaging Radiometer

(AVIRIS), for example, is designed to record reflected energy in the visible through middle-infrared portions of the spectrum by scanning 224 bands across a very narrow bandwidth. The Hyperion sensor on NASA's EO-1 satellite is

capable of providing spectral resolution of Earth's surface properties in 220 narrow spectral bands. A greater number of spectral bands available on hyperspectral sensors provide more spectral information about Earth's surface properties and are therefore capable of extracting even very subtle spectral information that usually cannot be resolved by multispectral sensors. Through these hundreds of very narrow-wavelength bands, fine spectral discrimination between different features on Earth's surface can be accurately achieved.

SPECTRAL TRANSFORMATIONS

Optical Earth remote sensing sensors record the reflected solar radiation in multiple discrete spectral channels, producing a spectral signature for each picture element in a remote sensing image. The amount of reflected energy depends on the physical and chemical nature and status of the object's surface and is a function of the scanned wavelength of the electromagnetic spectrum. The spectral information that is saved in different data layers can be treated separately (e.g., by displaying a single channel on the screen), or it can be combined in different ways, widely referred to as spectral transformations.

Any transformation of a multispectral data set generates a new image or a set of data channels

with the overall aim of maximizing the information content and at the same time minimizing the data load. The general concept of such transformations includes an accentuation of the dichotomies in the multispectral feature space with regard to specific objects (e.g., vegetation, soil, or atmosphere) or processing purposes (e.g., radiometric normalization, image classification, change detection, or estimation of biophysical properties).

Arithmetic Operations/Band Calculations

Arithmetic operations (addition, subtraction, multiplication, division) or band calculations can be carried out on any data set of at least two spectral bands of the same geographical area. They allow the generation of a new image with properties that are more suited to a particular purpose than the original ones. The most widely used arithmetic operation in remote sensing image analysis is the division or rationing of spectral bands with the aim of emphasizing the differences between them. These differences may be quantified to estimate, for example, the biophysical or geochemical properties of the land surface (see next section). Another widely used application of image division is the normalization of spectral response patterns by rationing two spectral bands. This technique makes use of the fact that illuminated surfaces reflect more solar radiation than shaded surfaces of the same nature and that the relation between those two can roughly be described by a multiplicative spectral component.

Many cases of band calculations combine at least two arithmetic operations, for example, image addition and division. For example, the average spectral reflectance in visible light (VIS) is calculated by summing the digital numbers of the respective channels in the blue, green, and red parts of the spectrum and dividing the sum by the number of bands (i.e., $VIS = (B + G + R)/3$).

A special case of band calculations is that of conditional operations that do not make use of the total amount of incoming data for a calculation but use a selection of the data set. An example is the common method of selecting the maximum spectral reflectance value for the same spectral band over the same geographical area out of a collection of n subsequent (e.g., daily)

data takes. This method, known as the maximum value composite method, is widely used in generating coarse-resolution temporal composites of global coverage remote sensing products (e.g., MODIS, Spot-VEGETATION, NOAA-AVHRR).

Spectral Ratios and Vegetation Indices

Spectral ratios describe a group of band calculations that use the spectral reflection in two bands. Modification and extension of ratios to multiple complex band calculations resulted in the emergence of the term (spectral) *vegetation indices* (VIs). This term accounts for the fact that the amount of solar radiation that is reflected from a land surface object is a function of wavelength and object characteristics, especially the type and biophysical properties of the vegetated fraction of the object (e.g., fraction-absorbed photosynthetically active radiation, chlorophyll, leaf area index, or biomass). In particular, VIs parameterize the relation between the absorption maximum in the red (R) region and the reflectance maximum of the near-infrared region (NIR) of the electromagnetic spectrum, which is characteristic of vital vegetation. These circumstances have led to the development of a vast number of VIs that are widely applied in any spatially explicit Earth science application of remote sensing data. Among others, the Normalized Difference Vegetation Index (NDVI) is representative of the group of dual-band VIs. It is the ratio of the difference of NIR and R to their sum:

$$\text{NDVI} = \frac{\text{NIR} - \text{R}}{\text{NIR} + \text{R}}.$$

Further development of VIs aimed at optimizing the results from the NDVI but in most cases showed high consistency with simple ratios or the NDVI. A second generation of VIs focused more on the elimination of the external factors influencing reflectance and VIs, such as atmosphere, viewing geometry, and soil background (e.g., SAVI, EVI, GEMI, and many more).

The main problem with the use of VIs in environmental studies is to select an appropriate VI for a specific application. The question of which VI should be used can only be answered based on reliable ground truth information.

Principal Components Transformation

Principal components transformation (PCT), also known as principal components analysis or Karhunen-Loeve analysis, is a technique that transforms the original multispectral remote sensing data set into a new set of uncorrelated variables (components) based on the covariance matrix of the n -dimensional input data set. In general, most of the information content of the original data set is represented by only a few new components, which enables considerable reduction in the dimensionality (i.e., the number of bands) in the data set.

Modified forms of the PCT include the minimum noise fraction procedure, which is more suited for hyperspectral data, and the noise-adjusted PCT.

Color Transformations

Color transformations are used to convert the color coordinate system of an RGB remote sensing data set to a different color space. Such transformations may be useful for printing purposes or for visualization of color composites of remote sensing data but, in most cases, are used for the fusion of remote sensing data of different types, for example, different spatial and spectral resolutions.

SPORTS, GEOGRAPHY OF

Sports throughout the world are influenced by both the physical and the human geographies of a given location. Despite this relationship and the wealth of potential research topics, geographers tend not to treat sports as a serious academic theme, although economists, sociologists, anthropologists, historians, and even psychiatrists have done so. This void is evident in the discontinuation of the only journal on sports geography—*Sport Place*—due to the lack of submissions. This intersection of sports and geography has been studied by geographers since the 1960s, first by John Rooney and more recently by John Bale. Today, there continues to be a small group of geographers who study sports.

Topics in the geography of sports cover a wide range of human as well as physical geography themes. The most common topic has dealt with the recruitment of players for sports teams at both the collegiate and the professional levels. Much can be learned from the spatial distribution of athletes in a given sport. Recent trends in North American sports suggest that leagues are globalizing and recruiting players from countries throughout the world. The National Basketball Association and the National Hockey League have long been able to attract players from outside North America, while Latin American players have been a staple in professional baseball for decades. More recently, major league baseball searched for new markets for producing players and exposure. This expansion is best represented by the World Baseball Classic, which began play in 2006. While the tournament includes countries with noted histories of playing baseball—the United States, the Dominican Republic, and Japan—it also includes newcomers to the sport, such as China and South Africa. These new markets serve not only as ways to find new prospects for teams but also as ways to market the leagues and their teams in other countries.

Sports have also played a significant role in geopolitics and nationalism. The Olympics have long been a stage for promoting national pride not only for the host countries but for participants as well. Examples of moments that have stirred patriotic sentiments include the U.S. men's ice hockey team's victory over the Soviet Union in the 1980 winter games and the unexpected fourth-place finish by the Iraqi men's soccer team in the 2004 summer games. The Olympics have also been used as a tool of protest, including the 1976 Montreal summer games, boycotted by numerous African states over apartheid-related issues, and the boycotts of the 1980 Moscow Winter Olympics and the 1984 Los Angeles summer Olympics by the United States and the Soviet Union, respectively. There were also calls to boycott the 2008 Beijing summer Olympics due to human rights concerns in China, although no boycotts took place. The Olympics are also used as a way of seeking legitimacy and recognition by new and aspiring states in the international community. In 2000, athletes from Timor-Leste (East Timor) competed in the Sydney summer Olympics despite not being recognized as a country (Timor-Leste was not independent until 2004). Palestine has also been represented in the summer Olympics since the 1996 Atlanta Olympics.

The political geography of sports goes beyond simply the Olympics. Sports have served as a way to ease political tension, as was the case with the so-called ping-pong diplomacy between the United States and China in 1971, a series of cricket test matches in the 2000s between India and Pakistan, or the 1999 two-game exhibition series played in Havana between Major League Baseball's Baltimore Orioles and the Cuban National Team. But as is the case with the Olympics, sports in general can be used as a way to protest against another country or even an individual. In 2009, the United Arab Emirates denied a visa to the Israeli tennis player Shahar Peer, thereby not allowing her to compete in a World Tennis Association tournament in Dubai.

Sports can also serve as a way of fostering a sense of identity and attachment. Whether it is high school football in Texas, hockey in Canada, baseball in Japan, or rugby in New Zealand, sports help create a common identity at local, regional, and national scales. Furthermore, sports

Japan's catcher Kenji Johjima (*right*) celebrates the final out after South Korea's Keunwoo Jeong (*left*) struck out in their World Baseball Classic game at Dodger Stadium in Los Angeles, March 23, 2009. Japan won 5–3.

Source: AP Photo/Mark J. Terrill.

and the associated teams can serve as a common identity for diasporic peoples, such as the “Red Sox Nation.”

Another important spatial aspect that geographers have researched in terms of sports is the location of sports franchises and their associated playing facilities. While shifts in population play a major role in the diffusion of franchises in North America, other aspects, such as the search for new markets, also serve to drive this expansion. The National Hockey League, for example, has expanded into (or relocated teams to) warm weather locales such as Los Angeles, Phoenix, Dallas, Atlanta, and Miami in recent decades. In terms of urban political economy, the location of sports stadia has reflected central city decline and redevelopment. From the 1960s to the 1980s, North American sports franchises tended to build

or had built for them new stadia and arenas in suburban locations, a reflection of urban population trends. Over the past 20 years, there has been a return to the central city, as sports facilities often serve as anchors to downtown revitalization projects.

Physical geography also plays a role in the performance of sports. High elevations have had a profound impact on sporting events, as they did in the 1968 Mexico City summer Games and the first decade of baseball in Denver. Teams have often taken advantage of their physical settings to create a home-field advantage, a concept that contains many human geographic elements. Examples of this physical advantage include the Bolivian national soccer team hosting World Cup qualifying games at La Paz (more than 3,500 meters above sea level) and the National Football

League's Tampa Bay Buccaneers wearing their white uniforms during home games to combat the relatively high temperatures of Florida. In the case of golf courses and ski resorts, sports can also reshape the physical environment.

While this is not an exhaustive list of the ways in which geography can shed light on various aspects of sports, it is clear that the two are complementary. There is much that geographers can contribute to the growing critical research that sociologists, economists, and historians of sport are already undertaking.

Squatter settlements are defined as residential areas built on vacant land, either private or public, in an unauthorized fashion. A typical squatter settlement is located on the fringe of a large city; the land is occupied illegally without legal title to it; the houses fail to conform to building codes and regulations; and the settlement lacks or has very limited infrastructure and services such as running water, electricity, sanitation, paved roads, and educational and medical facilities. There are other terms that are used interchangeably, such as *shanty towns* or *informal, spontaneous, irregular, unregulated, unauthorized, unplanned, or self-help settlements*, although each term has its own political implications. Sometimes it is their illegality, sometimes their unplanned nature, and sometimes their substandard qualities that are stressed by the terms used. Countries have their local terms for squatter settlements: *favelas* in Brazil (Portuguese), *barrios* in some other Latin American countries (many Latin American countries have their own terms, e.g., *barriadas* in Peru and *villas miseria* in Argentina), *bustee* in India, *bidonvilles* in Francophone West Africa, *kampong* in Southeast Asia, and *gecekondur* in Turkey.
